Abstract: In this paper we present an approach to improving navigability of a hierarchically structured Web content. The approach is based on an integration of a tagging module and adoption of tag clouds as a navigational aid for such content. The main idea of this approach is to apply tagging for the purpose of a better highlighting of cross–references between information items across the hierarchy. Although in principle tag clouds have the potential to support efficient navigation in tagging systems, recent research identified a number of limitations. In particular, applying tag clouds within pragmatic limits of a typical user interface leads to poor navigational performance as tag clouds are vulnerable to a so-called pagination effect. In this paper, a solution to the pagination problem is discussed, implemented as a part of an Austrian online encyclopedia called Austria-Forum, and analyzed. In addition, a simulation-based evaluation of the new algorithm has been conducted. The first evaluation results are quite promising, as the efficient navigational properties are restored.

Key Words: Tagging, tags, tag clouds, algorithm, tag cloud algorithm, navigation, navigability, online encyclopedia
Category: H.4

1 Introduction

An example of a semi-structured website is Austria-Forum[1]. Basically, Austria-Forum is a collection of several hierarchically structured Austrian encyclopedias that contain information about biographies, post stamps, coins, or the Austrian Universal Encyclopedia AEIOU[2]. Austria-Forum is a Wiki based system, whose articles within a single encyclopedia are hierarchically structured. Thus, Austria-Forum is also called a structured Wiki [Trattner et al. 2010]. Currently, as of 1^{st} of October 2010 the system provides over 130,000 information items to the user.

[1] `http://www.austria-lexikon.at/`
[2] `http://www.aeiou.at/`

Due to the hierarchical structure and the rapid growth of the system over the past few months, links between articles in different encyclopedias are sparse even though they might be related to each other. For example, there are several "Mozart" stamps in the Stamps encyclopedia. However, none of these articles has links to the "Mozart" biography, or "Mozart" coins because the articles are created and managed independently.

To tackle the problem of poor connectivity, a simple tagging mechanism was introduced to Austria-Forum [Trattner and Helic 2009]. In tagging systems people use free-form vocabulary [Hammond et al. 2005] to annotate resources with "tags" [Wu et al. 2006, Marlow et al. 2006, Us Saaed 2008]. This is either done for semantic reasons (e.g. to enrich information items with metadata), conversational (e.g. for social signaling) [Ames and Naaman 2007] or for organizational reasons (e.g. to categorize information items) [Körner et al. 2010]. Regardless of "why people tag" [Strohmaier et al. 2010, Nov and Ye 2010, Strohmaier 2008, Körner et al. 2010a], tags can be visualized in so-called "tag clouds". A tag cloud [Ames and Naaman 2007] is a selection of tags related to a particular resource. Upon clicking on a tag, a list of resources tagged with that tag is presented to users leaving them with a possibility to easily navigate to related resources. The main idea of including a tag module into Austria-Forum can best be described via the previously mentioned "Mozart" example. Suppose that users tag "Mozart" stamps, "Mozart" coins, "Mozart" biography, or any other document dealing with "Mozart" with a common tag, e.g. "Amadeus". Whenever users navigate to any of these articles a tag cloud containing all assigned tags is presented by the system. Thus, users can now click on "Amadeus" tag and this presents a list of all other articles tagged by that tag. Consequently, all articles tagged with "Amadeus" are now linked to each other, in fact, they are cross-linked across the hierarchical structure. Due to such indirect linking capabilities, tag clouds are sometimes applied to provide navigational support in tagging systems (cf. systems such as Flickr, Delicious, or BibSonomy).

Recently, in a number of studies tag clouds have been investigated from user interface [Mesnage and Carman 2009, Sinclair and Cardew-Hall 2008] and networktheoretic perspectives [Neubauer and Obermayer 2009]. These studies agree with regard to some interesting findings, such as the observation that current tag cloud calculation algorithms need to be improved. The ability of tag clouds to support "efficient" navigation under the consideration of pragmatic user interface limits, such as tag cloud size and pagination, is very poor [Helic et al. 2010]. In particular, the pagination effect causes the fragmentation of the network destroying the connected component and thus leaving a majority of resources unreachable.

In this paper, we present an approach to constructing tag clouds that support efficient navigation. This new algorithm is based on the idea of hierarchical

network models that are known to be efficiently navigable [Kleinberg 2001]. The algorithm has been implemented in Austria-Forum as a general tool for improving connectivity and navigability of the system as a whole.

The paper is structured as follows: Section 2 presents a model for tag cloud based navigation. Section 3 discusses the problems of tag cloud based navigation and current tag cloud construction algorithms. Section 4 presents the idea of a new and optimized tag cloud calculation algorithm based on the ideas of a hierarchical network model within an online encyclopedia system called Austria-Forum. Section 5 provides an analysis of the potentials and limitation of this new approach. Section 7 gives some insights to related work in this field. Finally, Section 7 concludes the paper and provides an outlook for the future work in this area.

2 Model of Tag Cloud Navigation

In this paper, the tagging data is modeled as a pair of the form (r, t), where r is a resource from the set of all resources R, and t is a tag of all tags T. Here, we do not take into account users as we concentrate only on links between resources imposed by tags assigned to those resources. The main navigational aid in a tagging system is a tag cloud and we denote it with TC. Formally, a tag cloud TC is a particular selection of tags from the tag set.

Due to user interface restrictions the number of tags within a tag cloud is usually limited to an upper bound. To model this situation we additionally introduce a factor n as a maximum number of tags in a tag cloud.

Usually, the most popular tags are assigned to a large number of resources – hundreds or even thousands of resources. When a user clicks on such a tag, tagging systems present a long paginated list of tagged resources. In most cases, 10–100 resources are presented to the users at once (see e.g. Delicious or Bibsonomy). To model these user interface limitation – that we refer to as the pagination from here on – we introduce a factor k that k-limits the resource list of tags within a tag cloud TC.

Finally, let us model the navigation process in a tagging system. Navigation in a tagging system might start from a home page where a system-global tag cloud is presented. Typically, tags with the highest global frequency are selected for inclusion in a tag cloud. Upon clicking on a particular tag a k-limited list of resources is shown. Once the user has selected a specific resource, the system transfers the user to the selected resource and presents a resource-specific tag cloud TC_r. The tags in such a resource-specific tag are selected according to the highest local frequency. In the next step, by selecting a tag from a given resource-specific tag cloud, the system again presents a paginated list of resources and the user might continue the navigation process in the same manner as before (see Figure 1).

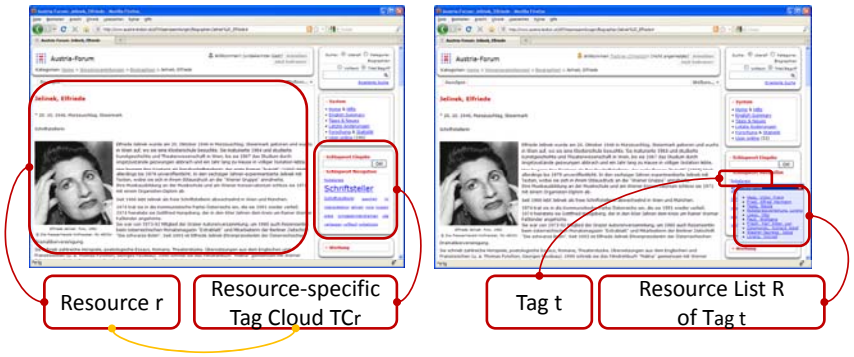

Figure 1: Resource specific tag cloud TC_r and k-limited resource list R of tag t within Austria-Forum

3 Problems of Tag Cloud Navigation

Resource-specific tag clouds are a simple way to connect resources within a tagging system, i.e. in a typical tagging system one can find nearly 99% of the resources interlinked with each other within a tag cloud network [Helic et al. 2010]. However, this simple approach to building tag clouds exhibits certain problems. In particular, resource-specific tag clouds are vulnerable to a so-called pagination effect [Helic et al. 2010]. In other words, by k-limiting the resource list of a given tag (with typical pagination values such as 5, 10, or 20), the connectivity of the tag cloud network collapses drastically. Practically, this leads to a situation where the tag cloud network consists of isolated network clusters (components) that are not linked to each other anymore. In other words, the users cannot reach one network fragment from another network fragment by navigating resource-specific tag clouds. One simple solution to this problem is to select resource for inclusion in a k-limited resource list uniformly at random [Helic et al. 2010]. For example, whenever the user clicks on a given tag in the tag cloud the system randomly selects k resources and presents them to the user. This leads to situation, that not always the same links are selected which leads to the situation that isolated network clusters are created [Helic et al. 2010]. As [Bollobás and Chung 1988, Helic et al. 2010] have shown this approach produces a random network that is, even for small values of k, completely connected.

3.1 Navigable vs. Efficiently Navigable Tag Cloud Networks

Another interesting issue in that context is the question if such randomly generated networks are also navigable. From a network-theoretic point of view

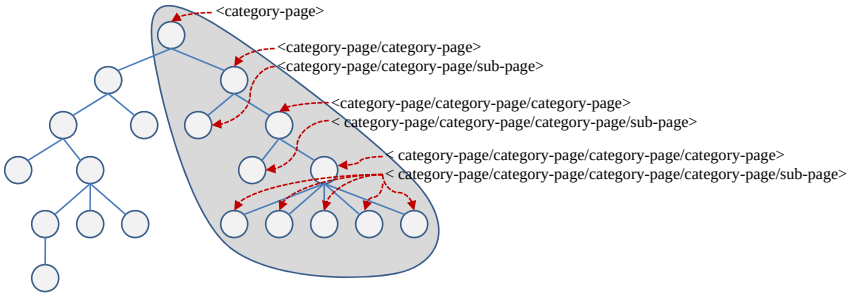

Figure 2: Hierarchical structure and URL addressing schema within Austria-Forum.

Kleinberg [Kleinberg 2000a, Kleinberg 2000b, Kleinberg 2001] showed that a navigable network can be formally defined as a network with a low diameter [Newman 2003] bounded by log(N), where N is the number of nodes in the network, and an existing giant component, i.e. a strongly connected component containing almost all nodes. Additionally, Kleinberg defined an "efficiently" navigable network as a network possessing certain structural properties so that it is possible to design efficient decentralized search algorithms (algorithms that only have local knowledge of the network) [Kleinberg 2000a, Kleinberg 2000b, Kleinberg 2001]. The delivery time (the expected number of steps to reach an arbitrary target node) of such algorithms is polylogarithmic or at most sub-linear in N. Put short, in [Kleinberg 2001] Kleinberg also showed that naive random networks algorithms form network structures which require linear search time ($O(N)$), i.e. in the worst case one has to visit all N nodes within a network to reach a certain destination node, i.e. such networks are not efficient navigable. However, in [Kleinberg 2001] Kleinberg also showed that hierarchical network models generate networks which are navigable in polynomial of $O(logN)$. Thus, we applied a hierarchical network model for tag cloud network generation in Austria-Forum to support efficient navigation.

4 Algorithm

4.1 Tag Clouds Hierarchy

We distinguish between two different types of nodes within Austria-Forum – category-page and sub-page nodes with sub-page nodes being hierarchy leaves (see Figure 2). Information items within Austria-Forum are hierarchically structured and addressable via a hierarchical URL schema.

The first component of the tag cloud generation algorithm in Austria-Forum simply follows the hierarchical data organization and constructs hierarchically organized tag clouds. The idea of this component is to provide more links between articles in one and the same category and to shorten the paths between category-pages and sub-pages. Thus, in order to generate a tag cloud for a particular category-page, the tags of all sub-categories and all sub-pages are aggregated recursively [Trattner and Helic 2009]. On the other hand, in order to generate a tag cloud for a particular sub-page, the resource-specific tag cloud calculation pattern is applied. The hierarchical tag cloud generation algorithm is shown in Algorithm 1 with t_f representing the local tag frequency.

Algorithm 1 Tag Cloud Calculation Algorithm

getTagCloud: url, n
if (url is category-page) **then**
  $TC_r^n \leftarrow$ select top n tags sorted by t_f where r.url.startsWith(url)
else
  $TC_r^n \leftarrow$ select top n tags sorted by t_f
end if
return TC_r^n

4.2 Addressing the Pagination Problem

Hierarchical network models [Kleinberg 2001] are based on the idea that, in many settings, the nodes in a network can be organized in a hierarchy. The hierarchy can be represented as a b-ary tree and network nodes can be attached to the leaves of the tree. For each node v, we can create a link to all other nodes w with the probability p that decreases with $h(v, w)$ where h is the height of the least common ancestor of v and w in the tree. Networks generated by this model are "efficiently" navigable [Kleinberg 2001].

The main idea of applying such a hierarchical network model is to reuse the hierarchical organization schema of articles in Austria-Forum as the basis for generating the link probability distribution p as described before. The hierarchical network model as introduced by Kleinberg takes a complete, balanced tree of nodes to obtain the link distribution. However, such an optimal model is typically not obtainable since real-word networks (cf. Open Directory Project[3], Google Directory[4] or Yahoo! Directory[5]) form hierarchical structures which are

[3] http://www.dmoz.org/
[4] http://directory.google.com/
[5] http://dir.yahoo.com/

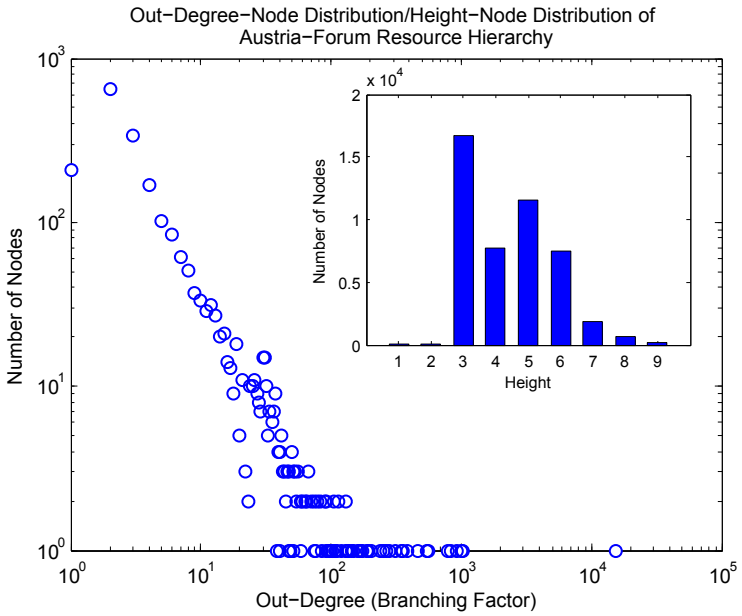

Figure 3: Out-degree distribution and node distribution of Austria-Forum resource hierarchy.

rarely complete nor balanced (cf. [Adamic and Adar]). For instance, in Austria-Forum the average branching factor is around 21 nodes ranging from 1 to over 14,000 nodes per category while the out-degree (branching factor) distribution of the hierarchy follows a power-law distribution (see Figure 3), which do not satisfy Kleinberg criteria such as a constant branching factor b. Thus, an algorithm implementing Kleinberg's model in our setting needs to work with intuitions and approximations.

The intuition which we followed with our algorithm is that the probability that an article is linked with other articles from the same category is higher than the probability that an article is linked with articles from other categories (cf. [Watts et al. 2002, Adamic and Adar, Kleinberg 2001]). Put short, this can be modeled by defining a link selection function that inter-links two nodes (articles) v, w according to a link probability function that is equal to $p = e^{-dist(v,w)}$ (cf. [Watts et al. 2002]) and a distance function that is calculated as $dist(v, w) = h_v + h_w - 2h(v, w) - 1$, where h_v, h_w are the heights of two nodes v, w in the hierarchy and where $h(v, w)$ is the height of the least common ancestor of the nodes v, w in the hierarchy (cf. [Adamic and Adar]). In Algorithm 2 the actual algorithm is presented.

Algorithm 2 Resource List Calculation Algorithm

For any given node $r(t) \in R$ in the resource hierarchy R, where t is the tag applied to this node, we find all other nodes $r_j(t) \in R$ and calculate distance $dist(r(t), r_j(t)) = h(r(t)) + h(r_j(t)) - 2h(r(t), r_j(t)) - 1$. For all found nodes $r_j(t) \in R$ we put $r_j(t)$ according to the distance $dist(r(t), r_j(t))$ into clusters $cl_x = [r_i, ..., r_j]$ and store these clusters into an array $rdist(i)_{r(t)} = [cl_{dist_1}, ..., cl_{dist_{n-1}}]$. Now, to select k links from the resource list, we generate k random numbers $i_k = 1$ ... sizeof$(rdist(i)_{r(t)})$ with a probability density function $p = e^{-x}$ with $x = 1$ ... sizeof$(rdist(i)_{r(t)})$ and select k clusters $cl_{i_k} \in rdist(i_k)_{r(t)}$ returning for each cluster just one element which is selected uniform at random.

5 Evaluation

To evaluate the presented algorithm, we developed a theoretical framework that integrates the following two modules:

- a **network-theoretic module** based on the Stanford Snap[6] library to calculate and evaluate network properties such as the size of the Largest Strongly Connected Component (LSCC) or the Effective Diameter (ED) [Helic et al. 2010] of the tag cloud network
- and a **searcher module** which implements a hierarchical decentralized searcher to simulate "efficient" tag cloud driven navigation.

5.1 Datasets

In the following section we describe the tag cloud networks which were generated and used for further evaluations. Basically, five different types of tag cloud networks were generated (see Table 1). They all vary in the way how the tag cloud and the resource list is calculated. Since one of our recent studies [Helic et al. 2010] showed that limiting the tag cloud to practically feasible sizes (e.g. 5, 10, or more) does not influence navigability, we set the tag cloud size in our experiments to a fixed value of $n = 30$ which is actually also the size of the tag clouds of Austria-Forum live system. Contrary, we varied the value k, i.e. the maximum number of links in the resource list, to $k = 15, 50, 100$, which is expected to impair navigability [Helic et al. 2010].

Dataset N (=Naive): This tag cloud network simulates the most common and naive tag cloud and resource list calculation approach used these days in tagging systems [Helic et al. 2010]. In other words, the tag cloud calculation algorithm in this model follows a simple TopN approach displaying the most

and the hierarchical resource list algorithm introduced in Algorithm 2.

5.2 Evaluating Navigability

In order to evaluate whether the generated tag cloud networks are navigable or not, the size of the largest strongly connected component (LSCC) and the effective diameter (ED) was calculated. As already defined before (see Section 3.1), we consider navigable networks to be networks that have a low diameter bounded logarithmically and a giant component. As shown in Table 2, naive constructed tag cloud networks (N_15 – N_100 and HN_15 – HN_100) are formally seen not navigable. This is the case, since these types of networks do not have a giant component containing nearly almost all nodes of the network. Contrary, all other networks form navigable network structures, i.e. they contain a giant component and an effective diameter that is bounded logarithmically. Note, networks built on such a hierarchical approach generate networks that have a lower diameter

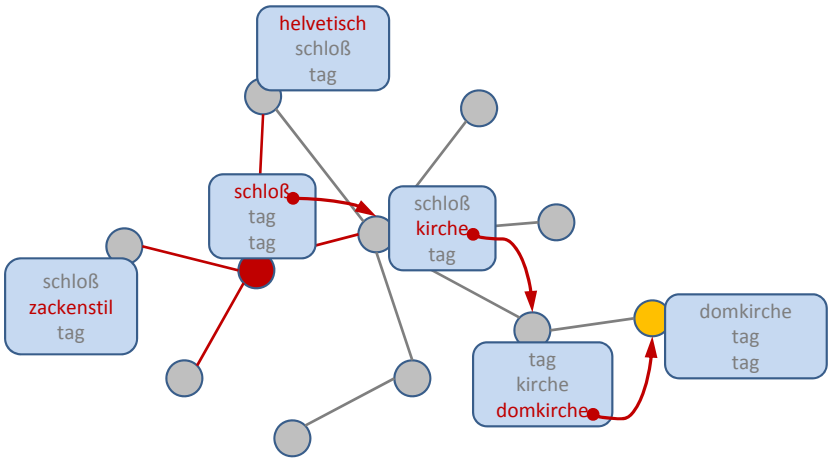

Figure 4: Shows an example of a resource-specific tag cloud network in Austria-Forum and a search through it.

than networks implementing a general TopN tag cloud calculation approach. This is not surprising, since such networks generate more long range links from category-pages to sub-pages, i.e. they shorten the paths to reach the sub-pages in the system.

5.3 Evaluating Efficiency

In order to evaluate the efficiency of our new approach, a hierarchical decentralized searcher was developed to simulate "efficient" tag cloud driven navigation. The searcher is basically an adoption of the work made by [Adamic and Adar] which uses background knowledge from the underlaying resource network structure to navigate the tag cloud network.

To model tag cloud based navigation, we define the tag cloud network as a bipartite hypergraph of the form $V = R \cup T$ [Helic et al. 2010], where R is the set of resources and T the set of tags. Since the resource lists are limited to a certain value k which forces the tag cloud network to collapse into a directed unipartite tag-resource network (with resource specific tags), we developed a searcher that walks along the underlying projected directed resource-resource network.

In Algorithm 3, the actual searcher algorithm is presented. In words, the algorithms works as follows:

To find a certain target resource w (e.g. tagged as "domkirche") from a certain start node v (e.g. tagged as "schloß") within the network (see Figure 4), the searcher first selects all adjacent nodes v_i for the start node and then

Algorithm 3 Hierarchical Decentralized Searcher (cf. [Adamic and Adar])

Searcher: resource-resource graph G, resource-hierarchy T, start node v, target node w
while v != w **do**
  $v_i \leftarrow$ get all adjacent nodes $\in G$ from v
  // finds closest node according to $dist = dist_{min}$
  // where $dist(v_i, w) = h(v_i) + h(w) - 2h(v_i, w) - 1$
  v $\leftarrow$ findClosestNode (v_i, T)
end while

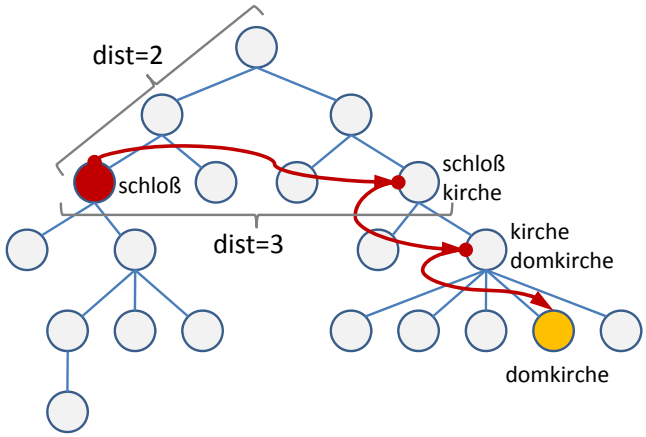

Figure 5: Shows an example of the Austria-Forum resource - taxonomy and a sample of tags they have applied.

selects the node v from the network ("kirche") that has the shortest distance $dist(v_i, w) = h(v_i) + h(w) - 2h(v_i, w) - 1$ to w node in the resource taxonomy T, with $h(v_i), h(w)$ being the heights of the two nodes v_i, w in the hierarchy and with $h(v_i, w)$ being the height of the least common ancestor of the two nodes v_i, w in the hierarchy [Adamic and Adar]. In the next step, the adjacent nodes of v are again selected and the distances $dist(v_i, w)$ are calculated, while the node v with shortest distance is selected in the end. The process is continued until the target node w is reached.

In order to get statistically significant results, we simulated 100,000 search-requests starting randomly selected at a certain resource v_i and targeting at certain randomly selected resource w_i in the tag cloud network. Note, only search pairs v_i, w_i were considered for the simulations for which a path (v_i, w_i) was present in the network. The upper limit for a search was set to a value of max-

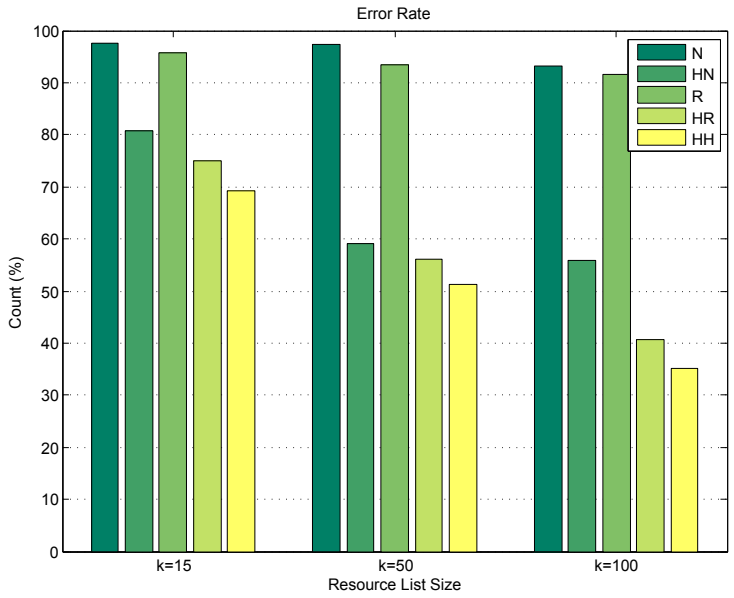

Figure 6: Error Rate for different types of networks. As expected, hierarchically generated networks (see network HG, HR and HH) perform significantly better than naive generated tag cloud networks (see network G and R).

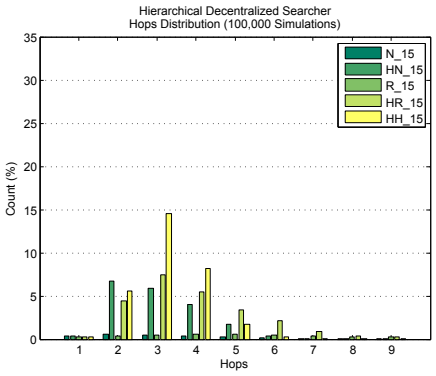
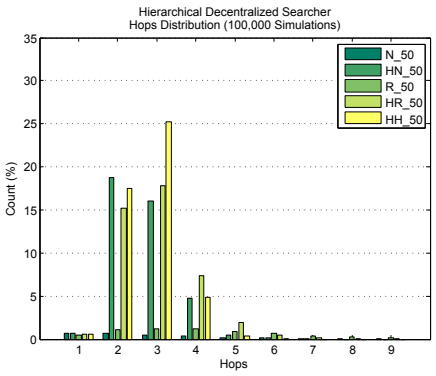
imum 100 hops in the simulations, i.e. we canceled searches which took more than 100 hops to find a target node w_i. If the searcher was not able to find a path further in the tag cloud network, we canceled the search task as well. If a search task was being canceled, we did not reset the searcher to find a new path for the same search pair v_i, w_i.

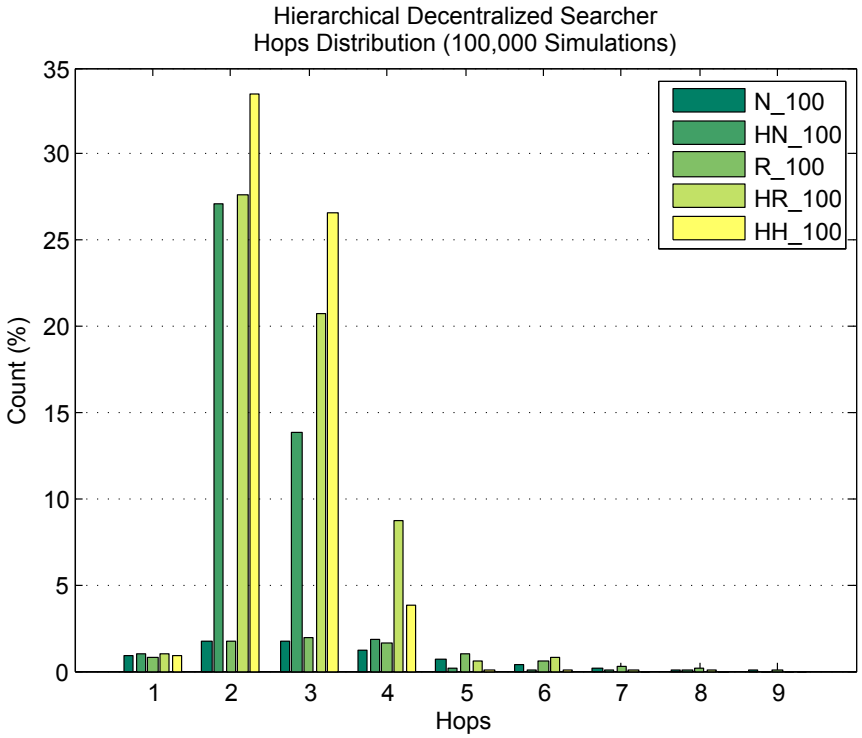
As shown in Figure 6, flat and paginated tag cloud networks (labeled as network G and R in Figure 6) produce poor results for a naive hierarchical search algorithm in such networks. The reason for this behavior is the fact that the searcher frequently lands on a sink in the tag cloud network. This is the case since the resource has already been visited before or there is no link offered by the resource the searcher can follow anymore due to the low number of links (see Table 1) because of the pagination effect. "Expanded" networks implementing a hierarchical tag cloud algorithm (see Algorithm 1) perform even better in finding paths from resources v_i to a resources w_i in the network. For instance, for paginated resource lists and hierarchically calculated tag clouds (cf. network N and NH in Figure 6), the searcher fails only in 27% of all cases, while without hierarchically calculated tag clouds the error rate of the searcher in more than



(a) k=15



(b) k=50



(c) k=100

Figure 7: Hierarchical Decentralized Searcher hop-distributions for different values of $k = 15, 50, 100$ (size of the resource list).

89%. Furthermore, we can observe that hierarchically randomly generated networks are better navigable than all other investigated approaches (see network HR and HH in Figure 6). This is the case, since such networks provide more links between the resources of a tagging system (see Table 1) than "flat" general networks. Finally, we can investigate that networks adopting a hierarchical resource list calculation algorithm (see network HH in Figure 6) perform best by means of navigation. In case of Austria-Forum, this type of tag cloud network generates the lowest error rate and the fastest searchable network (see Figure 7) among all others.

6 Related Work

In related research on tagging systems, tag clouds have been characterized as a way to translate the emergent vocabulary of a folksonomy into social navigation tools [Sinclair and Cardew-Hall 2008, Dieberger 1997]. Social navigation itself represents a multi-dimensional concept, covering a range of different issues and ideas. A distinction between direct and indirect social navigation, for example, highlights whether navigational clues are provided by direct communication among users (e.g. via chat), or whether navigational clues are indirectly inferred from historical traces left by others [Millen and Feinberg 2006]. Based on this distinction, our work only focuses on indirect social navigation in the sense that it studies the effectiveness of traces ("tags") left by users in tagging systems. Other types of social navigation emphasise the need to show the presence of others users, to build trust among groups of users, or to encourage certain behaviour [Millen and Feinberg 2006].

Researchers have discussed the advantages and drawbacks of tag clouds, suggesting that tag clouds are a useful mechanism when users' search tasks are general and explorative (for example, learn about Web 2.0), while tag clouds provide little value for specific information-seeking tasks (for example, navigate to www.cnn.com) [Sinclair and Cardew-Hall 2008]. While the paper at hand focuses on network-theoretic aspects, cognitive aspects of navigation have been studied previously using, for example, SNIF-ACT [Fu and Pirolli] and social information foraging theory [Pirolli 2009]. Other work has studied the motivations of users for tagging [Körner et al. 2010], and how they influence emergent semantic (as opposed to navigational) structures. The navigational utility of single tags has been investigated [Chi and Mytkowicz] with somewhat disappointing results. With time the tags become harder and harder to use as they lose specificity and reference too many resources. Such tags are exactly those paginated tags where new pagination algorithms are needed.

Navigation models for tagging systems have been also discussed recently. In [Ramezani et al. 2009] authors describe a navigation framework for tagging systems. The authors apply the framework to analyze possible attacks on tagging

systems. In principle, the framework identifies a navigation channels as any combination of the basic elements of a tagging system (users, tags, and resources). Thus, the specific combination which we investigated in this paper can be summarized as the resource-tag or tag-resource navigation channel.

Recent literature also discusses further algorithms for the construction of tag clouds. The ELSABer algorithm [Li et al. 2007] represents an example of such an effort aimed towards identifying hierarchical relationships between annotations to facilitate browsing. The work by [Aouiche et al. 2008] is another example, introducing entropy-based algorithms for the construction of interesting tag clouds. However, these algorithms have not found wide-spread adoption in current social tagging systems, and their usefulness to support navigation is largely unknown. In future work, it would be interesting to compare additional tag cloud construction algorithms with our approach. In addition, empirical studies of tagging systems have for example focused on comparing navigational characteristics of tag distributions to similar distributions produced by library terms [Heymann et al. 2010].

7 Conclusions and Future Work

The main contribution of this paper is the introduction of a novel, tag-based algorithm for interlinking resources in hierarchically-structured Web content. Based on a review of tag cloud limitations and an existing hierarchical algorithm for the construction of efficiently navigable networks, we discussed, implemented, and evaluated by simulation a new approach to tag cloud construction that improves the overall navigability of social tagging systems. While the arguments laid out in this paper are of a theoretical nature, we empirically tested the navigability of link structures produced by such an algorithm and confirmed the theoretical expectations by simulation. Finally, evaluating the usability and usefulness of the proposed algorithm with end users in an experimental setting would bring new insights into the potentials and limitations of the proposed approach.
