**Abstract** High speed devices for public key cryptography are of emerging interest. For this reason, the RSA $\alpha$  crypto chip was designed. It is an architecture capable of performing fast RSA encryption and other cryptographic algorithms based on modulo multiplication. Besides the modulo multiplication algorithm called *FastMM*, the reasons for its high computation speed are the *As Parallel As Possible* (APAP) architecture, as well as the high operation frequency. The RSA $\alpha$  crypto chip also contains on-chip RAM and a special-purpose control logic, enabling special features like encrypted key loading. However, this control mechanism influences to some extent testability of the MM data path which is the heart of the chip. For this reason, the RSA $\beta$  crypto chip has been designed to be able to evaluate the behaviour of the pure MM data path. In the following, we describe the strategies used with the RSA $\beta$  crypto chip for testing the MM data path under realistical conditions. In this context, analyzing control signal flow turns out to be the key action.

**Key Words:** high speed multipliers, hardware algorithms, design for testability, public key cryptography

### 1 Introduction

Simulating a CMOS VLSI design and testing the prototype of a newly designed chip is a sophisticated and time consuming task. This is in particular true in the special case of the RSA $\beta$  Crypto Chip, which has as its core a data path of rather high complexity for performing modulo multiplications (MM), organized as a bitslice SIMD architecture [Lippitsch et al (1992)]. Several reasons are responsible for the need of detailed testing:

- The modulo multiplier is built in modified domino logic [Weste et al (1993)], which results in smaller area and higher speed, but requires a very careful design process.

- The necessity for handling very large integers for a secure RSA implementation causes a width of the MM data path of about 700 bits. Designing CMOS circuits of this size leads to specific problems not present when designing much smaller systems.

Therefore, it is quite advisable to spend very much effort on simulating the chip’s function, and to provide built-in testing features. Furthermore, stand-alone testing of the MM data path without control logic driving it would be a preferable strategy.

We will concentrate on the last item. Real stand-alone testing of the MM data path in a separate package results in feeding its control signals directly via the chip’s pads. At this point, a problem arises: The maximum clock rate allowed by the pads is lower than the clock rate we would need at the MM data path to reach the desired processing speed by a factor of about 5. It makes no sense (and even might be impossible for dynamic logic) to test the MM data path at a much lower speed than it was designed for. Therefore we cannot avoid adding some kind of control logic between the pads and the MM data path.

Test results should not be influenced by that control structure. It should not cause any changes to the layout of the MM data path, and it must be of very high reliability. Both requirements call for an “as simple as possible” control structure. The key for finding such a minimum version of the control structure is to analyze the control signal flow, which allows for reducing redundancy, and even leads to the use of a modified version of the original modulo multiplication algorithm for optimizing control signal flow.

In this paper, we will take a closer look at the modulo multiplication algorithm (which is the heart of the RSA implementation), as well as at the MM data path designed for performing this operation efficiently. After analyzing the control signal flow, enough information is available to introduce a simple mechanism for compensating the clock rate difference without loss of overall performance. Finally, we will show an outline of a possible hardware implementation.

## 2 The FastMM Algorithm

The RSA algorithm [Rivest et al (1978)] performs both, encryption and decryption, by calculating

$$c = C^x \pmod{N},$$

with  $c$ ,  $C$  the cipher text and plain text or vice versa, and  $x$  the encryption or decryption key. To meet security demands, the modulus  $N$  must be of a length of approximately 700 bits. Exponentiation can be performed by the well known Square-and-Multiply algorithm [Knuth (1981)]. Therefore, for our purpose it is sufficient to consider the RSA implementation as a sequence of continued modulo multiplications with very long integers, separated by simple register transfer operations.

With the RSA $\beta$  Crypto Chip, modulo multiplication is done by the FastMM algorithm [Posch et al (1990)]. This algorithm performs

$$y = a \cdot b \pmod{N} + e \cdot N, \quad e \in \{0, 1, 2\},$$

which is much easier to compute than the exact modulo multiplication

$$z = a \cdot b \pmod{N},$$

as it avoids division and uses multiplication only like the Montgomery approach [Montgomery (1985)]. We will refer to  $y$  as *relaxed residuum*, since it is possibly not fully reduced.

The efficiency of FastMM is based on a fast and good approximation  $Q$  of the quotient  $q = \lfloor \frac{a \cdot b}{N} \rfloor$ , which is used to calculate the relaxed residuum

$$y = a \cdot b - Q \cdot N.$$

$Q$  is calculated as follows:

$$Q = \left\lfloor \left[ a \cdot b \cdot 2^{-(k-1)} \right] \left[ \frac{1}{N} \cdot 2^{2k+4} \right] \cdot 2^{-(k+5)} \right\rfloor$$

$k$  is the length of the modulus  $N$  in bits. For convenience, we introduce

$$NegN = -N$$

$$N1 = \left\lfloor \frac{1}{N} \cdot 2^{2k+4} \right\rfloor$$

Note that both,  $NegN$  as well as  $N1$  can be precomputed.

Now, FastMM can be represented using the following symbolic instructions ( $w[i]$  denotes the  $i$  rightmost bits of  $w$ ,  $[i]w$  denotes the  $i$  leftmost bits of  $w$ ):

$$X[2k+4] \leftarrow a[k+2] \cdot b[k+2] \tag{A}$$

$$Q[2k+10] \leftarrow N1[k+5] \cdot [k+5]X \tag{B}$$

$$y[k+2] \leftarrow NegN[k+2] \cdot [k+5]Q + X[k+2] \tag{C}$$

In [Posch et al (1990)] it is shown that the results of continued relaxed modulo multiplications never exceed the limit given by  $\epsilon$ . Therefore, only after the last multiplication a final modulus reduction might be necessary. Obviously, this reduction step does not decrease throughput, compared to the hundreds of modulo multiplications which are to be performed for getting the relaxed result. This final modulus reduction can be done by adding  $NegN$  to the result. Note that  $NegN$  and the possibility to perform an addition are needed by the FastMM algorithm, anyway. Therefore, the final modulus reduction requires no additional hardware effort or constants.

### 3 The MM Data Path

#### 3.1 The Structure of the MM Data Path

The design of the MM data path, shown in [Figure 1], meets the special requirements of the FastMM algorithm. It consists of several main registers with length 696 bits (**I0**, **Cph**, **Mkd**, **NegN**, **N1**, **Low**, **High**), an APAP-structure [Lippitsch et al (1991)] (described in [Section 3.2]) and a few auxiliary registers of length eight bits. **Adder-1** and **Adder-2** are needed for converting the redundant number representation — used by register **High** and the APAP-adder — into binary numbers. **Adder-3** performs the addition of multiplication step (C). The purpose of the transmission gates as well as the overall function of the MM

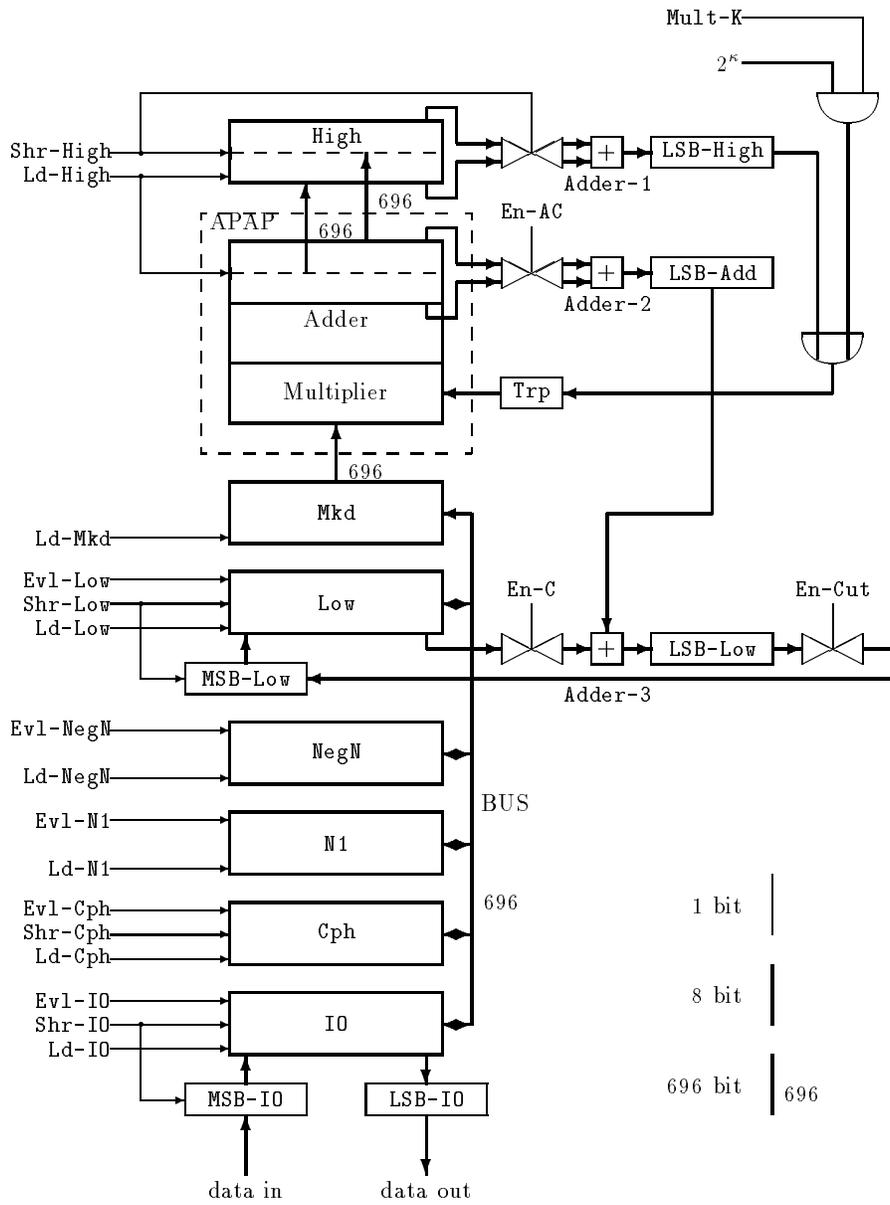

Figure 1: The MM data path

data path will become clear in [Section 3.3].

We will use the main registers in the following way: The **IO** register is needed for input/output operations, **Cph** (for *cipher text*) is commonly used for storing the last result while the next modulo multiplication is running. **NegN** and **N1** hold the corresponding constants mentioned in [Section 2], **Mkd** must contain the actual multiplicand. **Low** receives the lower part of the result of a multiplication in binary number representation, while **High** gets the higher part in redundant number representation.

The MM data path requires quite many control signals, denoted as a *control word*.

We present a complete list of the control signals which shows the actions in each clock cycle if the corresponding signal is active:

**Ev1-X**: Write value of register *X* to the 696 bit bus, where *X* can be one of the following: **IO**, **Cph**, **NegN**, **N1**, **Low**.

**Ld-Y**: Load register *Y* with the value of the 696 bit bus, where *Y* can be one of the following: **IO**, **Cph**, **NegN**, **N1**, **Low**, **Mkd**.

**Ld-High**: Load register **High** with the current value of the APAP-adder, then clear the APAP-adder.

**Shr-High**: Enable storing the least significant byte of register **High** to **LSB-High**, then shift **High** to the right by one byte.

**Shr-Low**: Shift **Low** to the right by one byte, including **MSB-Low**.

**Shr-IO**: Shift **IO** to the right by one byte including **MSB-IO**, thus loading a new byte from outside via **MSB-IO**.

**LSB-IO** buffers the least significant byte of **IO** and provides it for output.

**Shr-Cph**: Shift right **Cph** by one bit.

**En-AC**: Enable storing the least significant byte of the APAP-adder to **LSB-Add** during operation (A) resp. (C) of FastMM.

**En-C**: Enable storing the least significant byte of register **Low** to **LSB-Low** during operation (C) of FastMM.

**En-Cut**: Cut off the bit stream on changing from high to low.

**2<sup>κ</sup>**: Eight bits, holding the value of 2<sup>κ</sup>.

**Multi-K**: Load register **Trp** with 2<sup>κ</sup> for multiplying with **Mkd**.

### 3.2 The APAP-Structure

The APAP (**A**s **P**arallel **A**s **P**ossible)-structure represents a mixture of a serial/parallel multiplier and a full parallel Wallace tree multiplier [Wallace (1964)]. This approach has been chosen because for long integer arithmetic conventional serial/parallel multipliers would be far too slow, whereas a full Wallace tree multiplier cannot be implemented on reasonable chip area with current technology. The degree of parallelism (i.e., the number *p* of new partial products that can be processed each cycle) may vary between certain boundaries, which allows for scaling the APAP design. To avoid carry delays, redundant number representation is used.

For our purpose, we hide these implementation details, since we are only interested in the overall understanding of control signal handling. Therefore, we consider the APAP-structure together with **Adder-2**, as well as **High** together with **Adder-1** to be “black boxes”, thus hiding the internal function of the APAP-adder and the redundant number representation. (However, for

understanding the timing of the control signal sequence, the number of cycles consumed by the APAP-adder and **Adder-1** resp. **Adder-2** would have to be known.) Multiplication can now simply be described as a serial/parallel multiplication, where  $p$  bits of the multiplier are processed each cycle. For the RSA $\beta$  Crypto Chip,  $p = 8$  has been chosen.

The following example [Figure 2] provides such a pure behavioural description

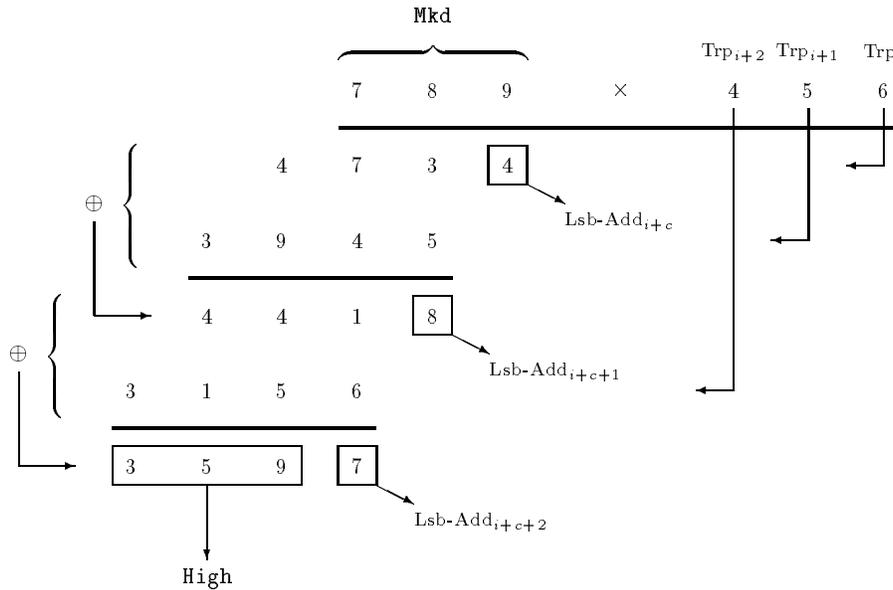

Figure 2: Multiplication scheme

of the multiplication procedure. It uses decimal digits instead of bytes, showing the principle of calculating the product of the multiplicand 789 and the multiplier 456.  $Reg_n$  denotes the content of *Reg* at the  $n$ th cycle;  $c$  is a positive constant depending on the APAP-structure and the adders.

The APAP-adder gets the first partial product (PP) by multiplying the multiplicand (held in **Mkd**) with the least significant digit of the multiplier. Note that the least significant digit of this PP represents the least significant digit of the the final result and can be loaded into **Lsb-Add**. Therefore, this PP is shifted to the right by one digit, being aligned for the addition with the PP of the next multiplication cycle as well. The least significant digit of the result of that addition represents the next digit of the result, and so forth. After the multiplicand has been multiplied with the most significant digit of the multiplier, the APAP-adder contains the higher part of the result, which can be loaded into **High**.

Note that the APAP-adder always shifts its content to the right by one byte

each cycle, while **Low** resp. **High** can be forced by the corresponding control signals to do so. It is important to understand that the MM data path is able to perform these actions in parallel: For example, while the APAP–multiplier is fed from **High** via **Trp** with a sequence of bytes to multiply, former multiplication results may be shifted into register **Low**. There are concurrent data streams, and their flow is controlled by a few control signals.

### 3.3 Performing a Modulo Multiplication with the MM Data Path

operation	action	Mkd	High	Low
<b>Mult-2<math>\kappa</math></b>	$b \rightarrow \text{High}$		$b[k+2]$	
	$a \rightarrow \text{Mkd}$	$a[k+2]$		
<b>Mod-Mul</b>	Mult. step (A)	$a[k+2]$	$[k+5]X$	$X[k+2]$
	$N1 \rightarrow \text{Mkd}$	$N1[k+5]$	$[k+5]X$	$X[k+2]$
	Mult. step (B)	$N1[k+5]$	$[k+5]Q$	$X[k+2]$
	$NegN \rightarrow \text{Mkd}$	$NegN[k+2]$	$[k+5]Q$	$X[k+2]$
	Mult. step (C)	$NegN[k+2]$		$y[k+2]$

**Table 1:** The FastMM scheme with the MM data path

Table 1 shows the overall scheme of the modulo multiplication with the MM data path. Once registers **NegN** and **N1** are loaded with the corresponding constants, the multiplier  $b$  must get into **High**. Figure 1 shows that this can only be done by loading it into **Mkd** first, followed by a multiplication by one. We will call this operation **Mult-2 $\kappa$** , because we assign the correct value to  $\kappa$  (in this context we consider  $\kappa = 0$ ) and set **Mult-K** to high for one cycle. This way, the content of **Mkd** gets multiplied with one (i.e.,  $2^\kappa$ ), and must be loaded from the APAP–adder into **High** at the very right moment, since the APAP–adder is shifting its content permanently.

After loading **Mkd** with the multiplicand  $a$ , we can start with operation **Mod-Mul**, the modulo multiplication using the FastMM algorithm. Figure 3 — which shows the control signal waveforms of a 664-bit modulo multiplication simulation — can now be understood:

We start multiplication step (A) with setting high **Shr-High** to feed the APAP–structure with the multiplier byte by byte. **En-AC**, **En-Cut** and **Shr-Low** are also set to high for shifting the lower part of the intermediate result into **Low**; it will be needed in step (C). When the higher part of the result is ready, it is loaded into **High** by activating **Ld-High**. At the same time, **N1** can be loaded into **Mkd**, starting multiplication step (B). This step is similar to step (A) except that shifting the result into **Low** is omitted. Step (C) starts with loading **NegN** into **Mkd** and is equal to step (A), but additionally sets **En-C** to high, thus adding the lower part of the multiplication result with the previous content of **Low**. After this procedure, the final result can be fetched from **Low**.

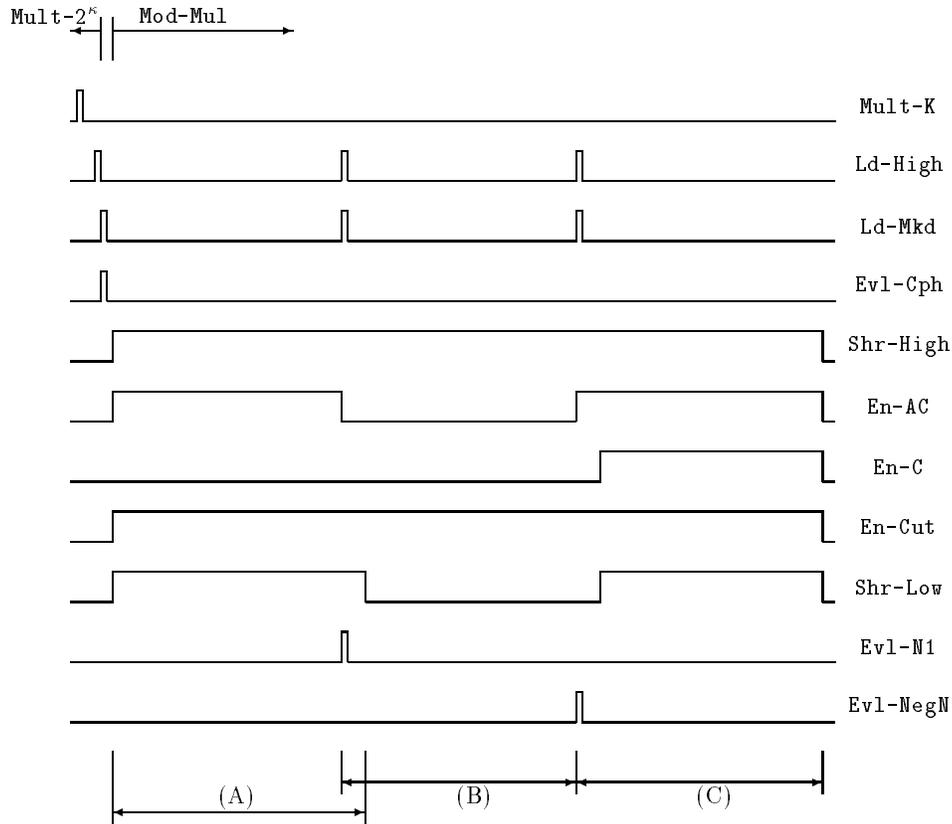

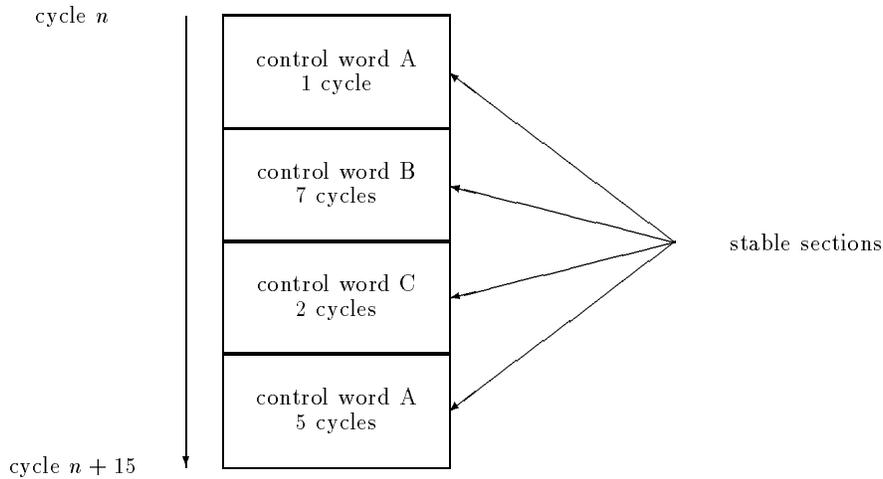

Figure 3: Timing diagram of the control signals during  $\text{Mult-}2^k$  and  $\text{Mod-Mul}$

### 3.4 Observations about the Control Words

We note that the two operations  $\text{Mult-}2^k$  and  $\text{Mod-Mul}$  work correctly if and only if their related sequences of control words appear in a given order with a given timing; in particular, the control words within these two operations must not be separated by any additional control word, not even by a NOP (that is, a control word which performs no operation onto the MM data path). That is because the flow of the different data streams will proceed with the internal clock, and synchronization with external feeding of control words is to be assumed at given cycles. Obviously, a wrong product would be calculated otherwise. We will refer to such a non-interruptable sequence of control words as an *atomic sequence*.

We further note that throughout the algorithm some control words are repeated several times. These sections will be referred to as *stable sections*.

With respect to [Section 5] it is useful to consider an atomic sequence as a sequence of stable sections, where the number of the stable sections is called the

**Figure 4:** An atomic sequence, consisting of several stable sections

*depth* of the atomic sequence. Figure 4 shows an atomic sequence of a length of 15 cycles and depth 4.

#### 4 A Modification of the FastMM Algorithm: FastMM\*

A closer look at the FastMM algorithm shows that truncation of intermediate results is necessary. For reasons of regularity it would be easier to implement truncation only at multiples of  $i$  bits rather than at arbitrary positions. With FastMM, values would generally be cut off at positions  $\neq i \cdot n$ .

To facilitate implementation, a solution of this problem is given by a method called *preshifting*. With this method, constants  $NegN$  and  $N1$  as well as  $a$  and  $b$  are preshifted to the left by certain values. Loading the multiplier into **High** is done by using a  $\kappa \neq 0$  when performing operation **Mult-2 $\kappa$** , thus shifting the multiplier to the left by  $\kappa$  bits for aligning at a desired border. After the modulo multiplication is finished, a final alignment is necessary to get the correct result. Furthermore, **En-Cut** must be able to truncate at arbitrary bit borders rather than at a position  $i \cdot n$ .

It is needless to mention that these additional procedures make the handling of the control signals more complicated. Therefore, the lengths of stable sections within the atomic sequence of operation **Mod-Mul** are shortened, increasing the depth of the atomic sequence — this is disadvantageous, as we will see in [Section 5]. For that reason, we would prefer an algorithm which avoids these difficulties.

The obvious goal in algorithm design is to minimize depth for a given algorithm by control word rearranging. A solution is given by a modified version of FastMM, called FastMM\*.

FastMM\* consists of the following steps:

$$\begin{aligned} X &\leftarrow a \cdot b \\ Z &\leftarrow M1 \cdot \frac{X}{2^{shift_1}} \\ y &\leftarrow NegN \cdot \frac{Z}{2^{shift_2}} + X \end{aligned}$$

The basic idea is to apply shifts only to constants which can be performed in advance. This algorithm has the same structure as FastMM, but uses a different constant  $M1$  instead of  $N1$ . Preshifting will not be necessary because  $shift_1$  and  $shift_2$  can be determined to meet the conditions  $shift_1 \equiv 0 \pmod{i}$  and  $shift_2 \equiv 0 \pmod{i}$ . Typically, one chooses  $i = \log_2 r$ , where  $r$  is the radix on which the long integer hardware is operating. The goals defined above can be achieved by calculating  $M1$ ,  $shift_1$  and  $shift_2$  in the following way:

$$\begin{aligned} adj2 &= (k - 1) \bmod i \\ adj1 &= i - ((k + 5 + adj2) \bmod i) \\ shift1 &= k - 1 - adj2 \\ shift2 &= k + 5 + adj1 + adj2 \\ M1 &= 2^{2k+4+adj1} \cdot \frac{1}{N} \end{aligned}$$

$k$  is the length of the modulus  $N$  in bits.

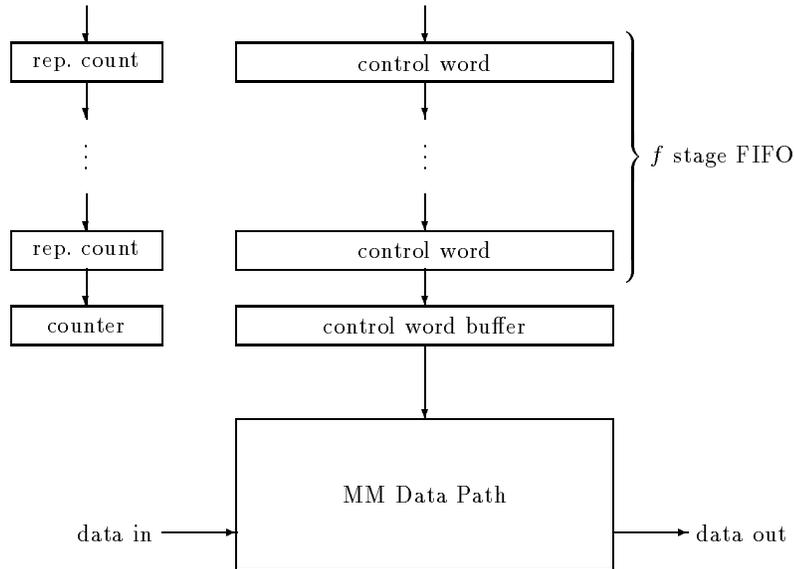

A further benefit of FastMM\* is that it allows optimization in terms of the possibility to change more control signals at the same time (i.e., a higher degree of parallelism) than with FastMM. This results in a significant reduction of the depth of the atomic sequence associated with **Mod-Mul**. Additionally, for FastMM\*  $\kappa$  is always 0, therefore control signals associated with  $2^\kappa$  may be omitted.

## 5 Managing the Clock Rate Difference Using a FIFO

In this section, a method for compensating the difference between the maximum clock rate allowed by the pads and the clock rate of the MM data path is presented.

First, data flow at the control signal interface will be reduced. This can easily be done because the MM data path doesn't need to be fed with one control word each cycle if we use stable sections instead. Each stable section is described by the corresponding control word and the number of cycles it is "stable" [see figure 4]. The control structure between the pads and the MM data path now consists of a buffer for the control word, and a down counter to decide when to fetch the control word of the next stable section. That would be sufficient if each stable section consisted of enough cycles, ensuring that continuous fetching of control words never exceeds the maximum clock rate allowed by the pads.

Unfortunately, there are a lot of stable sections consisting only of a few cycles. Therefore, a mechanism has to be added which feeds internally generated NOPs into the MM data path until the next control word is available. Otherwise, control words could influence the MM data path in a wrong way. However, this will still not work because atomic sequences must not be interrupted by NOPs. (The problem arises because of the existence of atomic sequences which contain stable sections of length one, as we will see in [Section 5.1].) The

**Figure 5:** A FIFO for compensating the clock rate difference

solution is to add a FIFO between the pads and the control word buffer [see figure 5]. Inserting NOPs in between an atomic sequence can be prevented by preceding each atomic sequence with an externally inserted NOP as the control word, and a repeat count big enough to fill the FIFO with the stable sections of the entire atomic sequence. When the down counter expires, the stages of the FIFO are shifted, and the counter gets the next repeat count as start value. Internally generated NOPs will only reach the MM data path if the FIFO is cleared before the next external control word could reach the control word buffer. Therefore, the depth of the FIFO must not be lower than the depth of the longest atomic sequence.

As will be shown in [Section 5.2], analyzing atomic sequences of FastMM\* allows for reducing this depth.

## 5.1 Atomic Instruction Sequences of FastMM\*

For observing the control word flow at the MM data path, a simulation environment has been developed. This environment uses *GENIE*<sup>1</sup> for controlling the simulation of an RSA encryption with *Lsim*<sup>2</sup>. The simulation is based on an functional *M*<sup>3</sup>-model of the MM data path.

The use of the procedural simulation interface provided by *GENIE* has several advantages:

- Simulation runs of high complexity can be controlled and evaluated by using a C-like language, thus allowing a higher level of abstraction than with conventional methods.
- Straightforward observation of the 696 bit wide MM data path becomes enabled.
- One can get the sequence of stable sections (that is, the control words and the associated number of cycles) for a modulo multiplication totally automatic.
- Flexibility in controlling the simulation simplifies extracting the atomic sequences.
- Once the simulation environment is “debugged”, the occurrence of errors when analyzing the interface is minimized.

Using this environment, the control signal interface of the MM data path can easily be analyzed for different algorithms as well as for different implementations of the same algorithm. Additionally, it supplies the control words needed for controlling a test chip which uses the proposed FIFO.

	Control Word	Repetitions
1	0180000 <sub>h</sub>	0
2	0100000 <sub>h</sub>	1
3	0104000 <sub>h</sub>	0

**Table 2:** Stable sections of **Mult-2<sup>n</sup>**

In [Table 2] and [Table 3], the atomic sequences for **Mult-2<sup>n</sup>** and **Mod-Mul** of a full 664 bit modulo multiplication are shown. For each stable section the first value represents the control word, the second value the required repeat count. We observe that **Mod-Mul** calls for a FIFO of at least depth 9. This result is only valid for the FastMM\* algorithm; as mentioned in [Section 4], the FastMM algorithm would increase depth significantly.

<sup>1</sup> *GENIE*<sup>TM</sup> (**G**eneral **I**nterpreted **E**nvironment) is a general-purpose interpreted language well-suited for use as a control language attached to application programs like *Lsim*.

<sup>2</sup> *Lsim*<sup>TM</sup> is a *MentorGraphics*<sup>R</sup> design automation tool that allows to analyze the behaviour of electronic designs ranging from high-level, abstract system models through full-custom integrated designs.

<sup>3</sup> *M* is a hardware description language for describing the behaviour of circuits in functional models, for use with the *Lsim* simulator.

	Control Word	Repetitions
1	0158020 <sub>h</sub>	88
2	014E420 <sub>h</sub>	0
3	0148020 <sub>h</sub>	6
4	0148000 <sub>h</sub>	81
5	015F000 <sub>h</sub>	0
6	0158000 <sub>h</sub>	5
7	0178020 <sub>h</sub>	85
8	0124020 <sub>h</sub>	0
9	0120020 <sub>h</sub>	1

**Table 3:** Stable sections of **Mod-Mul**

## 5.2 Reducing Depth of the Instruction FIFO

Having in mind [Table 3], we are able to introduce some optimizations. Since **Mod-Mul** starts with a control word which is repeated many times, this atomic sequence doesn't need to be preceded by an externally inserted NOP; the FIFO will be filled, anyway. Thus, waste of execution cycles can be reduced. That is true because we made the implicit assumption  $T_e/T_i \leq r$ , where  $T_e$  is the external cycle time (the maximum cycle time allowed by the pads), and  $T_i$  is the internal cycle time the MM data path uses. It seems to be adequate to assume  $r = 5$ .

A closer look at [Table 3] shows that for  $r = 5$  a FIFO of depth 3 is sufficient because within **Mod-Mul** there are stable sections long enough to prevent clearing out the FIFO. This depth also satisfies **Mult-2<sup>r</sup>**.

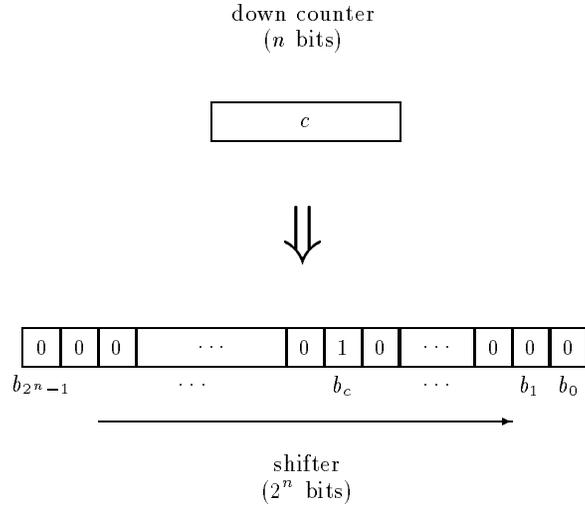

A second possible method to reduce the depth of the FIFO is to split the atomic sequence associated with **Mod-Mul** into three shorter atomic sequences associated with the multiplication steps (A), (B) and (C). This method adds extra cycles to the entire modulo multiplication, but does not lead to a smaller FIFO than the first method does. Because speed of the modulo multiplication is the bottleneck of an RSA implementation, that method is not of prime interest.

## 6 An Outline of the Hardware Implementation

Using a FIFO for controlling the MM data path meets the goal of having an "as simple as possible" control structure for testing purposes. It would be quite consistent to avoid extremely complex design methods when implementing the FIFO in hardware. For the same reason, shifting the contents of the FIFO stages is chosen to be done synchronously rather than asynchronously.

The clock of the MM data path is used, since the FIFO must operate at the same (high) speed. This high speed seems to be the only substantial difficulty when designing the FIFO circuit layout.

As we have seen in [Section 5], a down counter will be needed. It has to fulfil the given timing constraints: decrementing, detecting underflow, setting up load signals for the stages and shifting the stages must work within a single cycle. Therefore, the down counter is replaced by a shifter, as shown in [Figure 6]. This

**Figure 6:** Replacing the down counter by a shifter

way, much of time is saved because shifting a single bit works a lot faster than decrementing a counter, and no decoder is necessary for detecting whether the next control word has to be loaded; this can be done by inspecting the single bit  $b_0$ . To avoid an excessively long shifter, its length can be decreased by limiting the repeat count to a certain power of two, thus splitting long stable sections. On the increasing FIFO depth resulting thereof and the length of the shifter a good compromise has to be evaluated.

Figure 7 shows a schematic diagram with a FIFO of depth 4. Precise timing issues are omitted; in particular, the circuit for the handshake signal timing has to be designed carefully. Special attention has to be paid to the asynchronous **Strobe** input to avoid metastable states and synchronization failure.

The handshake procedure works in the following way: If the top FIFO stage is empty, **Busy** is set to low, indicating a request for the next control word. The positive edge of **Strobe** signals that the next control word is available from outside, and sets **Busy** to high. For the time **Busy** is low, internal NOPs with repeat count 0 are to be inserted. This is done by “anding” the input signals with **Busy**. Additionally, the **Ext** bit is cleared, indicating an internally generated NOP. If **Busy** is high and the load signal for the top stage is set, there must have been a rising edge of **Strobe** (because the load signal resets **Busy**). In that case, the top stage is loaded from outside.

Load signals are generated as follows: Expiration of the shifter means to load all stages. If any stage is marked as an internally generated NOP, it should be overwritten at the next cycle, and all stages above have to move down; with other words, the decision for shifting an upper stage depends on the state of all underlying stages. This results in cascaded **OR** gates, shown in [Figure 7]. Remember there is only one cycle for setting up all load signals, therefore serious

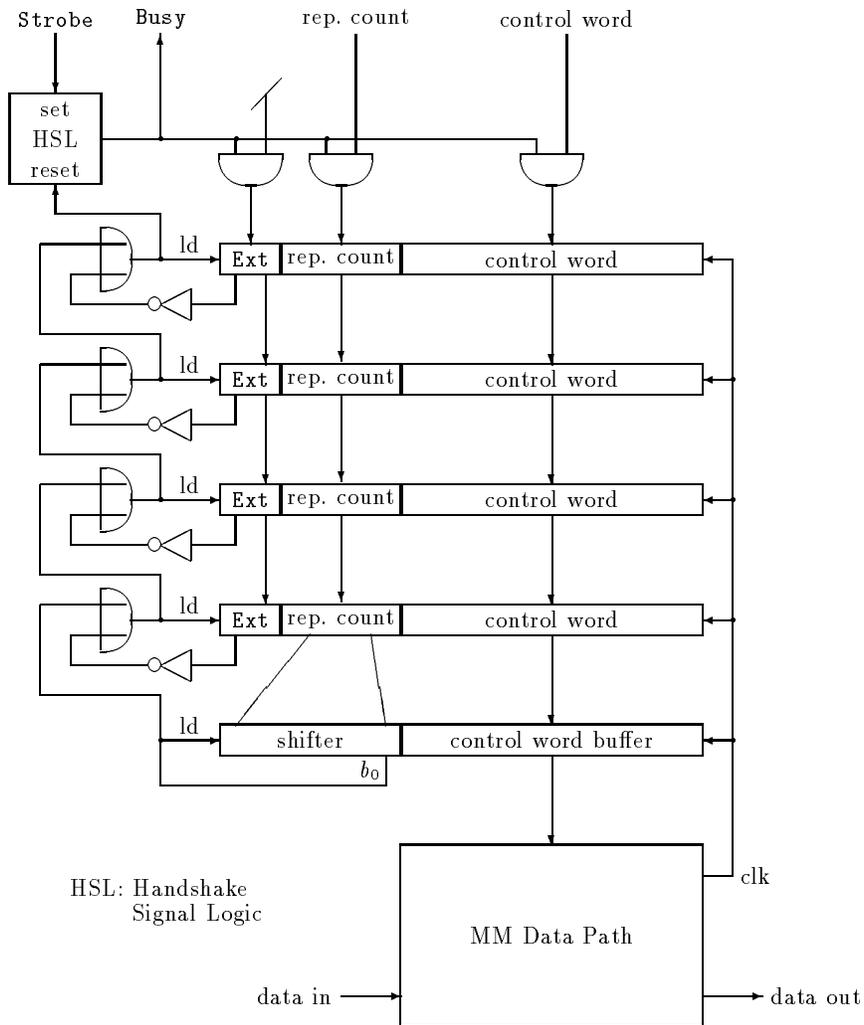

Figure 7: Schematic diagram of the FIFO

delays caused by cascaded gates must be avoided.

## 7 Conclusion

In order to design a chip for testing the MM data path, we searched a minimum version of the control structure. After analyzing the data flow at the control interface, we introduced a FIFO for compensating the difference of the maximum clock rate allowed by the chip's pads, and the clock rate the MM data path

requires to reach the desired encryption rate.

Simulation results for a complete 664 bit RSA run based on  $M$ -models of the FIFO and the MM data path showed that it is sufficient to precede the whole sequence of multiplications with only a few NOPs, if we use the FastMM\* algorithm and do not reduce the depth of the FIFO as described in [Section 5.2]. In this case, not even a single additional NOP needs to be inserted in between that sequence of multiplications. Because almost all cycles of a complete RSA run are needed for that sequence of multiplications, overall performance is not significantly affected by a slow clock rate at the pads. Therefore, if there is no need to reduce the depth of the FIFO (e.g. for shrinking down its size to save chip area), an RSA chip using the proposed control structure might be appropriate even beyond testing purposes.
