

‘Computing’ as Information Compression by Multiple Alignment, Unification and Search

J Gerard Wolff
(University of Wales, Bangor, UK
gerry@sees.bangor.ac.uk)

Abstract: This paper argues that the operations of a ‘Universal Turing Machine’ (UTM) and equivalent mechanisms such as the ‘Post Canonical System’ (PCS) - which are widely accepted as definitions of the concept of ‘computing’ - may be interpreted as *information compression by multiple alignment, unification and search* (ICMAUS). The motivation for this interpretation is that it suggests ways in which the UTM/PCS model may be augmented in a proposed new computing system designed to exploit the ICMAUS principles as fully as possible. The provision of a relatively sophisticated search mechanism in the proposed ‘SP’ system appears to open the door to the *integration* and *simplification* of a range of functions including unsupervised inductive learning, best-match pattern recognition and information retrieval, probabilistic reasoning, planning and problem solving, and others. Detailed consideration of how the ICMAUS principles may be applied to these functions is outside the scope of this article but relevant sources are cited in this article.

Key Words: Theory of computing; Turing machine; Post canonical system; multiple alignment; new computing paradigms.

Category: SD F.0

1 Introduction

For about 60 years, it has been widely accepted that the intuitive concept of ‘computing’ may be defined in terms of the operations of a ‘Universal Turing Machine’ (UTM, [Turing 36-7]) and concepts which are recognised as equivalent such as the ‘Lambda Calculus’ (Church and Kleene, see [Rosser 84]), ‘Recursive Function’ [Kleene 36], ‘Normal Algorithm’ [Markov and Nagorny 88] and Post’s ‘Canonical System’ (PCS, [Post 43]). These and related ideas have been phenomenally successful, providing the theoretical basis for the design of most modern digital computers.

However, notwithstanding Turing’s own vision of the possibility of artificial intelligence [Turing 50], the UTM and the PCS and equivalent models of computing operate in a rigid ‘clockwork’ manner which appears far removed from the fluidity of human intelligence. Likewise, ordinary digital computers, without special programming, are notoriously lacking in human-like flexibility and intelligence.

Because the UTM and equivalent models, and a conventional computer in ‘raw’ state, have so little functionality and so little intelligence, it is necessary for practical purposes to create programs which provide the missing capabilities, as far as these are understood. Although our understanding is still very patchy, there is increasing success with AI applications in achieving human-like capabilities such as speech recognition, the ability to play games like chess, go or

bridge, the ability to recognise visual patterns and objects in a flexible manner, and others.

Since computers were first invented, much effort has been devoted to the development of programs and associated concepts across a wide range of applications. Many areas of application are now quite well served by specialised programs. However:

- Notwithstanding the development of 'suites' of programs intended to work together, there are still many problems of integration between different kinds of application.
- Similar concepts have emerged in diverse forms. For example, the concept of 'heuristic search' manifests itself in the form of 'hill climbing' (or 'descent'), 'genetic algorithm', 'simulated annealing', 'dynamic programming', 'neural computation', and others. Without normally being recognised as such, heuristic methods also appear in 'standard' computational techniques such as the Newton-Raphson method for finding square roots, dynamic programming and techniques for matching patterns and retrieving information.
- The diversity of programs and concepts is collectively, very complex. There is a need for rationalisation and simplification across diverse areas.

1.1 New developments

These considerations have been the main motivation for a programme of research ([Wolff 90] to [Wolff 99]) seeking new insights into the nature of computing, and aiming to develop a 'new generation' computing system based on these ideas.

If we can identify the elements which are shared by diverse applications and abstract them from the elements which are truly specific for each application, this may help us to achieve an overall simplification of computing systems and better integration across applications. It can mean less programming - and thus less cost - and there should be less opportunity to introduce errors - yielding gains in quality.

As we shall see (Section 2), the central idea in this research is the conjecture that "all kinds of computing and formal reasoning may usefully be understood as *information compression by multiple alignment, unification and search* (IC-MAUS)". This is still only a conjecture and may turn out to be wrong. But there is already an accumulation of supporting evidence described and discussed in sources cited in Section 1.2.

The use of the word "theory" for these proposals (Section 2) may suggest that they are intended to displace established theories of computing. It is more accurate to say that the proposals are a framework of ideas which provide an interpretation for established models of computing and which suggest ways in which those models may be augmented to provide additional functionality which is generic for many applications.

As a test-bed for these ideas and a vehicle for demonstrations, a software model has been developed, SP61, running on a conventional computer. This is described briefly in Section 2.6 and more fully in sources cited there. All the alignments shown in this paper are output from the model.

1.2 Scope and orientation of this paper

Regarding the primary motivation for these developments - to promote simplicity and integration in computing - no attempt will be made in this paper to demonstrate the potential of these ideas. Readers are referred to the following sources describing how the ideas may apply in diverse areas of computing:¹

- Background thinking (the pervasive nature of information compression in human cognition and also in artificial computing): [Wolff 93].
- Unsupervised inductive learning:
 - The entire programme of research is based on a previous programme of research into unsupervised inductive learning of language ([Wolff 88, Wolff 82] and earlier articles cited in these two articles).
 - A demonstration of how an early form of the framework of ideas may be applied to learning is presented in [Wolff 95b].
 - Integration of unsupervised inductive learning and different kinds of reasoning: [Wolff 96].
- Best match information retrieval: [Wolff 99, Wolff 94a].
- The design and execution of software: [Wolff 94b].
- The potential range of applications of the SP concepts: [Wolff 95a, Wolff 95b].
- Causality: [Wolff 97].
- Parsing of natural language and representing the structure of natural language in the ICMAUS framework [Wolff 98d1, Wolff 98d2, Wolff 98d3].
- Probabilistic reasoning in the ICMAUS framework [Wolff 99, Wolff 98a, Wolff 98b, Wolff 98c], including:
 - Representing class hierarchies and inheritance of attributes.
 - Best-match pattern recognition and information retrieval.
 - Probabilistic 'deductive' reasoning.
 - Probabilistic abductive reasoning.
 - Reasoning with probabilistic decision networks and decision trees.
 - Reasoning with probabilistic if-then rules.
 - Reasoning with default values and nonmonotonic reasoning.
 - Solving geometric analogy problems.
 - Modelling the functioning of a Bayesian network.

The primary purpose of this paper is to describe the SP theory in outline, to show how it may provide an interpretive framework for the UTM and PCS, and to describe how those models may be augmented for greater generic functionality.

Apart from Appendix A, the presentation is relatively informal with examples to make the ideas clear. No attempt has been made to present a formal proof that the ICMAUS framework may model any UTM/PCS, largely because a detailed proof would take far more space than is available here.

¹ The papers before 1996 were written at a stage before the 'multiple alignment' insights were achieved (see Section 2, below).

1.3 Presentation

In what follows:

- Section 2 describes, in outline, the SP theory as it has been developed to date, together with some brief remarks about working models of the system.
- Section 3 describes, briefly, the concept of a UTM and, more fully, the equivalent concept of a PCS.
- Section 4 tries to show how the operation of a PCS (and, consequently, the operation of a UTM) may be interpreted in terms of ICMAUS concepts.
- Section 5 considers how established models of computing may, with advantage, be augmented.
- Section 6 contains concluding remarks.
- Appendix A defines the key terms used in this article.

2 The SP theory

As already indicated, the central idea in the 'SP' theory is the conjecture that:

All kinds of computing and formal reasoning may usefully be understood as information compression by multiple alignment,² unification and search.

Information compression (IC) may be interpreted as a process of maximising *Simplicity* in information (by reducing redundancy) whilst retaining as much as possible of its non-redundant descriptive *Power*. Hence the mnemonic 'SP' which has been applied to these ideas.

In this programme of research:

- The term *multiple alignment* (MA) has a meaning which is related to but distinct from its meaning in bio-informatics (where the term is normally used). The meaning of the term in this programme of research is explained below (Section 2.2).
- The term *unification* means a simple merging of matching symbols and sequences of symbols, a meaning which is related to but simpler than the concept of 'unification' in logic (where it means the assignment of values to variables in two structures so that the two structures become the same). As explained more fully below (Section 2.3.3), the unification of matching *patterns*³ is the core of the mechanism by which information is compressed.

² In earlier publications, the conjecture was expressed with the words 'pattern matching' in place of the words 'multiple alignment'. However, in the last few years, it has seemed appropriate to focus more narrowly on multiple alignment (which is one form of pattern matching) as the most promising framework (with unification and search) for the intended integration of concepts.

³ The meaning of the term *pattern* in this research is defined in Appendix A. It includes the meaning of the term *sequence* but it is more general because it includes arrays of symbols in two or more dimensions and it includes sequences (and other arrays) which are discontinuous. However, in most contexts in this article, the term *pattern* may be read as synonymous with the term *sequence*.

Conjecturally, it is the *sole* mechanism by which information may be compressed - meaning that *all* other mechanisms may be seen to contain unification at a fundamental level. More research is needed to establish whether or not this conjecture is true.

- In this context, the term *search* means the systematic exploration of the abstract space of possible multiple alignments. This can mean exhaustive search of the entire space of possible alignments but, as amplified below, for most practical problems, there must be some kind of *constraint* which reduces the size of the abstract space being searched.
- As we shall see (Section 3.3), the conjecture about the nature of computing, above, depends on at least one key assumption about how IC is measured. It also needs to be qualified by the observation that, to be practical, the process of searching for MAs that yield 'good' IC, it is sometimes necessary to examine MAs yielding ICs which are zero or negative (see Section 2.4.2).

2.1 Minimum Length Encoding and unsupervised inductive learning

The SP theory incorporates one version of the principle of 'Minimum Length Encoding' (MLE)⁴ from the field of inductive inference (see [Solomonoff 64, Wallace and Boulton 68, Rissanen 78, Li and Vitányi 97]). MLE is itself a version of 'Occam's Razor'.

The key idea in MLE is that, **in measuring compression, we must measure the size of the raw data in its encoded form together with the size of the code patterns which are needed to create the encoding**. Of course, if one or other of these components is constant (as is the case with all the examples considered in this article) then, for purposes of comparison, it is only necessary to measure the one which varies.

If both components can vary then, if either of them is omitted, counter-intuitive anomalies can arise. For example:

- We may create a code pattern comprising the entire contents of the works of Shakespeare with a one-bit label. Given that code pattern, we can compress the complete works of Shakespeare into one bit.
- Alternatively, we can create a set of code patterns comprising the letters and other characters used to print the text of Shakespeare. In this case, the set of code patterns is very small but encoding the works of Shakespeare using these patterns gives a result which is the same size as the original!

Clearly, any realistic compression of the Shakespeare text falls somewhere between these two extremes. Minimising the overall size of the set of code patterns and the encoded text seems to produce the required balance.

In connection with the discovery and development of these ideas, [Solomonoff 97] writes:

"I was trying to find an algorithm for the discovery of the 'best' grammar for a given set of acceptable sentences. One of the things I sought was:

⁴ MLE is an umbrella term for concepts of 'Minimum Message Length' encoding (MML) and the closely related 'Minimum Description Length' encoding (MDL).

Given a set of positive cases of acceptable sentences and several grammars, any of which is able to generate all the sentences, what goodness of fit criterion should be used? It is clear that the 'ad hoc grammar', that lists all of the sentences in the corpus, fits perfectly. The 'promiscuous grammar' that accepts any conceivable sentence, also fits perfectly. The first grammar has a long description; the second has a short description. It seemed that some grammar half-way between these, was 'correct' - but what criterion should be used?"

As indicated above, the key seems to be to minimise the overall size of the 'grammar' (repository of code patterns) together with the text which is encoded in terms of the grammar.

Similar ideas have been developed in computer models designed to test whether or not 'statistical' mechanisms might provide an explanation of some aspects of what children can apparently achieve when they learn their first language (see [Wolff 88, Wolff 82] and earlier papers referenced there):

- There is evidence that children can learn the segmental structure of language (words, phrases, sentences) without needing explicit markers at the beginnings and ends of these structures or explicit teaching.
- In a similar way, they appear to be able to 'bootstrap' their knowledge of word classes and other disjunctive categories in language without the aid of a teacher or other assistance.
- Apparently without the need for external supervision or correction, children can learn to distinguish 'correct' generalisations of grammatical rules from 'incorrect' overgeneralisations despite the fact that, by definition, both kinds of generalisation have zero frequency in the child's experience.

The models that have been developed (described in the sources cited above) appear to provide solutions to these problems and, as a by-product of the way they work and without *ad hoc* provision, exhibit several features in their learning which correspond remarkably well with a range of phenomena observed when children learn their first language. This empirical evidence is reviewed in [Wolff 88].

2.2 Multiple alignment

The term *multiple alignment* is normally associated with the computational analysis of (symbolic representations of) sequences of DNA bases or sequences of amino acid residues as part of the process of elucidating the structure, functions or evolution of the corresponding molecules.

The aim of the computation is to find one or more *alignments* which are, in some sense, 'good'. What 'good' can mean is discussed briefly below (Section 2.3).

An *alignment* is an arrangement of two or more sequences of atomic symbols so that, by judicious 'stretching' of sequences where appropriate, symbols that match each other are arranged in vertical columns.

As a matter of presentation, it is sometimes convenient to allow some columns to contain symbols that do not match each other and in this case vertical lines between symbols are used to mark where there are positive matches (*hits*) between the symbols. An example of an alignment of DNA sequences which uses this second convention is shown in Figure 1.

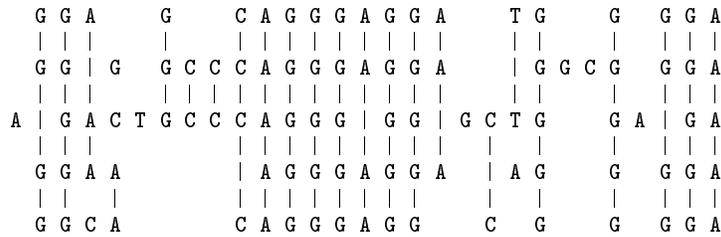

Figure 1: A 'good' alignment amongst five DNA sequences.

2.2.1 Generalisation of the concept of multiple alignment

In this research, the concept of MA has been generalised in the following way:

1. One (or more) of the sequences of symbols to be aligned has a special status and is designated as 'New'.
2. All other sequences are designated as 'Old'.
3. Alignments are evaluated in terms of the compression of New that can be achieved by encoding New in terms of sequences in Old, with or without the hierarchical encoding of tags mentioned in Section 2.3.1, below. A detailed description of how this can be done is presented in [Wolff 98a, Wolff 98d2] with a somewhat less detailed description in [Wolff 99].
4. An implication of this way of framing the alignment problem is that, by contrast with 'multiple alignment' as normally understood in bio-informatics, any given sequence in Old may appear two or more times in any one alignment and may therefore be aligned with itself (with the obvious restriction that any one instance of a symbol may not be aligned with itself).

Regarding the last point, the kind of MA shown in Figure 1 can obviously include two or more *copies* of a given sequence in any one alignment. It is unlikely that anyone would bother to do this in practice because it would simply lead to the trivial alignment of each symbol in one copy with the corresponding symbol or symbols in the one or more other copies.

What is proposed for the ICMAUS framework is different: any *one* sequence may appear two or more times in an alignment. Each appearance is just that, it is an *appearance* of *one* sequence, it is *not* a duplicate *copy* of a pattern.

Since each appearance of a pattern represents the same pattern, it makes no sense to recognise a hit between a symbol from one appearance and the corresponding symbol in another appearance - because this is simply matching one instance of the symbol with itself. Any such match is spurious and must be forbidden. However, it is entirely possible to recognise a hit between a symbol from one pattern and a *different* symbol from the same pattern. Examples will be seen later.

2.2.2 A simple example

To give the reader a flavour of the concept of multiple alignment as it has been developed in this research, a very simple example (from [Wolff 98d1]) is presented

here showing how parsing may be understood in these terms.

Figure 2 shows a 'grammar' for a fragment of English syntax presented as *patterns* as defined in Section A1. This particular example models a context-free phrase-structure grammar (CF-PSG) except that there is no rewrite arrow and each pattern has a number (shown in brackets on the right) which is its notional frequency of occurrence in a parsing of a sample of English.⁵

```

S N #N V #V #S (1000)
N 0 j o h n #N (300)
N 1 s u s a n #N (700)
V 0 w a l k s #V (650)
V 1 r u n s #V (350)

```

Figure 2: A simple grammar written as patterns of symbols. For each pattern, there is a number in brackets on the right representing the frequency of occurrence of the pattern in parsing of a notional sample of the language.

Figure 3 shows an MA which may be interpreted as a parsing of the sentence 'j o h n r u n s' in terms of the grammar in Figure 2. In parsings like this, the sentence to be parsed plays the role of New and the grammar used for parsing is treated as Old. By convention in these kinds of MA, the pattern which is New occupies the first row of the alignment and relevant patterns from Old are shown in the second and subsequent rows, one pattern per row.

```

0           j o h n           r u n s           0
           | | | |           | | | |
1  N 0 j o h n #N           | | | |           1
           |
2 S N           #N V           | | | | #V #S 2
           | | | | |
3           V 1 r u n s #V           3

```

Figure 3: Parsing of the sentence 'j o h n r u n s' as an alignment amongst sequences representing the sentence and relevant rules in the grammar in Figure 2.

2.3 Evaluation of alignments in terms of information compression

Intuitively, a good alignment is one which has many *hits* (positive matches between symbols), few *gaps* (sequences of one or more symbols which are not part

⁵ Despite the similarity, in this example, with a CF-PSG, this mode of representing syntax appears to have the kind of context-sensitive expressive power which is needed to represent the syntax of natural languages and which is missing from CF-PSGs (see [Wolff 98d1, Wolff 98d2, Wolff 98d3]).

of any hit) and, where there are gaps, they should be as short as possible. It is possible to use measures like these directly in computer programs for finding good MAs and, indeed, they commonly are. However, our confidence in the validity of measures like these may be increased if they can be placed within a broader theoretical framework.

In keeping with the remarks about IC, above, it seems that IC, and related concepts of probability,⁶ may provide that framework. Work on the evaluation of MAs in this tradition includes [Reichert *et al.* 73, Felsenstein 81, Chan *et al.* 92, Allison and Wallace 94, Allison *et al.* 92, Wolff 94a].

In the present proposals, MAs are also evaluated in terms of IC. However, owing to the way in which the concept of multiple alignment has been generalised (Section 2.2.1, above), the way in which alignments are evaluated in terms of IC, described in outline next, is somewhat different from methods used elsewhere.

2.3.1 Encoding New in terms of codes for patterns in Old

There is insufficient space to explain in detail how alignments are evaluated in terms of IC in the present scheme. Detailed explanation and examples showing how this can be done with multiple alignments can be found in [Wolff 98d2, Wolff 98a] with somewhat less detailed accounts in [Wolff 98d1, Wolff 99]. This subsection describes the method in outline.

In Figure 3, 'j o h n' in New is aligned with 'N 0 j o h n #N' in Old. It should be intuitively clear that we can encode this part of New using the 'code' symbols 'N 0 #N'. Likewise 'r u n s' may be encoded as 'V 1 #V'. Thus the whole sentence may be encoded as 'N 0 #N V 1 #V' with a modest reduction from 8 symbols to 6 (assuming, for the sake of simplicity in this example, that all symbols are encoded with the same number of bits).

However, the pattern 'N 0 #N V 1 #V' contains the subsequence 'N #N V #V'. And this subsequence is contained within the pattern 'S N #N V #V #S' - which is one of the patterns in Old. This means that the subsequence 'N #N V #V' may be encoded as 'S #S'. Thus the sequence 'N 0 #N V 1 #V' may be reduced to 'S 0 1 #S', preserving the symbols '0' and '1' to encode 'j o h n' and 'r u n s' respectively.

This encoding at two 'levels' (the sentence level and the word level) has the effect of reducing the original 8 symbols to 4. It should be clear that, with more complex examples, the same principles may be applied recursively through any number of 'levels'.

Regarding the MLE principle (Section 2.1) that measures of compression should include both the size of the 'grammar' used for coding and the size of the data after encoding, this is true in the context of systems that learn - where the size of the grammar is changing. As was noted previously, this need not apply in examples like the ones considered in this article, where, in each example, the size of Old remains constant. In these cases, for purposes of comparison, we may ignore the size of Old.

⁶ Variations in the probability of symbols and patterns has a key role in compression methods such as Huffman coding or Shannon-Fano-Elias coding (see [Cover and Thomas 91]). Conversely, measures of information content after compression can be used to calculate probabilities (see [Solomonoff 97, Wolff 99, Wolff 98a, Wolff 98b, Wolff 98c]).

2.3.2 Taking account of the probabilities of patterns and symbols

To present the method simply, this outline has assumed that every symbol is encoded with the same number of bits as every other symbol. However, the method used in the SP61 model (see Section 2.6, below) calculates the encoding cost of each symbol individually, taking account of its frequency of occurrence using a formula based on the Shannon-Fano-Elias (S-F-E) method (See [Cover and Thomas 91]). Of course, encoding costs calculated in this way are totally unrelated to the numbers of characters used in the names of symbols. Names of symbols are used purely for the sake of human comprehension and readability.

The sizes of codes assigned to patterns may, in a similar way, be related to their frequencies of occurrence using the S-F-E method or the Huffman method or something similar. However, for reasons which would take too much space to explain here, the SP61 model determines the size of the code for each pattern from the sizes of the symbols which are used in the code for the given pattern. This yields code sizes which are roughly in line with the principle that rare patterns should have longer codes than common patterns but the result is not as precise as with Huffman and similar methods.

2.3.3 The role of unification in information compression

It may seem too natural and 'obvious' to command much attention but the essence of the compression just described is the merging or *unification* of two or more sequences of symbols to make one. At the lowest level, 'j o h n' from New is, in effect, unified with 'N 0 j o h n #N' from Old. At the next level, 'N #N V #V' from two of the patterns in Old is unified with 'S N #N V #V #S', also from Old.

It is this unification of matching patterns, with or without the use of 'codes' or 'tags' to show where information has been deleted, which provides the foundation of all the simpler 'standard' methods for IC (see [Storer 88]) and, by conjecture, all other methods as well.

In the ICMAUS scheme, the touchstone of whether the necessary unifications can be applied is whether or not an alignment can be 'projected' into a single sequence without any ambiguity about the left-to-right sequence of the symbols. In the example shown in Figure 3, the alignment can be projected into a single sequence, thus:

S N 0 j o h n #N V 1 r u n s #V #S.

In this projection, each symbol corresponds to a column in the alignment and, in each column containing two or more symbols, the symbols have been unified to make one. Every column has a place in the alignment which ensures that its left-right position relative to other columns is not ambiguous.

2.3.4 'Mismatched' in alignments

By contrast with the example just given, the two 'nonsense' alignments shown here:

a	b		a	b		
a	x	b	and	a	b	x
a	y	b		a	b	y

exhibit ambiguity about the relative left-to-right positions of 'x' and 'y'. This means that neither of the alignments can be projected into a single sequence without making arbitrary choices, not supported by the data, about whether 'x' should precede 'y' or *vice versa*.

This kind of ambiguity in an alignment is described, in this research, as a 'mismatch' of symbols. In the ICMAUS scheme as it has been developed to date (and the SP61 model in which the scheme has been expressed) any alignment containing one or more mismatches between symbols in Old is discarded. It is possible, of course, to devise some scheme for resolving this kind of conflict using some kind of measure of 'strength' or 'support' for each of the two alternatives. At present, however, the theory in its current form does not provide any motive for this kind of manoeuvre and there seems not to be any need for it. Thus, pending new insights which might dictate a different course of action, any alignment of this kind is simply discarded.

In the ICMAUS scheme as currently conceived and also in the SP61 model, mismatches between symbols in New and symbols in Old are taken to mean simply that the offending part of New cannot be encoded in terms of the given alignment. Alignments with this kind of mismatch are permitted in the ICMAUS scheme and seem to be necessary in most parsing applications so that larger alignments encoding relatively large parts of New can be built from smaller ones which encode relatively small sections of New.

2.3.5 Information compression and Algorithmic Information Theory

In Algorithmic Information Theory (see, for example [Li and Vitányi 97]), a body of information is deemed to be random if no computer program can be found to generate the information which is smaller than that body of information. This elegant approach to defining randomness (which has advantages over earlier concepts of randomness) suggests that information compression should be defined in terms of relative sizes of computer programs.

The types of encodings described above may not look much like computer programs but there are remarkably close parallels between the devices used in structuring computer programs and the devices used for information compression. It would take too much space to discuss this here but readers may find a relatively full discussion in [Wolff 93].

2.4 Search

It is generally understood that, in multiple alignment problems, the abstract space of possible alignments (and corresponding unifications) is normally too large to be searched exhaustively. For example, the size of the search space for alignments of one sequence (A) of length m with another sequence (B) of length n is:

$$\Psi = \sum_{i=1}^m \sum_{j=1}^n (a_i \times b_j)$$

where a_i is the number of subsequences of length i within A and b_j is the number of subsequences of length j in B, and a_i is calculated as:

$$a_i = \frac{m!}{i!(m-i)!}$$

and likewise for b_j , substituting n for m . Even in simple cases like these, the size of the search space grows exponentially with the size of the patterns. In general, search spaces are astronomically large except when patterns are very few and very short.

2.4.1 Constraints on search

Because the entire search space for an MA is normally so very large, it is necessary for practical purposes to constrain the search in some way so that only a part of the search space is examined. In broad terms, this can be done in two different ways (which may be applied singly or together):

- More or less arbitrary constraints may be applied. For example, a limit may be placed on the maximum size of any gap (sequence of unmatched symbols) in any alignment. All other alignments are excluded from consideration. With this kind of constraint, certain parts of the search space are ruled out *a priori* and can never be reached.
- The second kind of constraint is applied in 'heuristic' techniques like 'hill climbing' ('descent'), 'beam search', 'genetic algorithm', 'simulated annealing' and so on. These techniques use some kind of measure of 'goodness' to narrow the space which is to be searched in successive stages. For this reason, they are sometimes known generically as 'metrics-guided search'. With heuristic techniques, the space which is to be searched can be dramatically reduced but no part of the total search space is ruled out *a priori*.

With constraints like these, there is normally a trade-off between the 'quality' of the best solutions found and the thoroughness of the search. With these kinds of technique, ideal solutions can be guaranteed only when examples are *very* small. However, with examples of realistic size, narrowing the search space as described above can yield good approximate solutions without excessive computational demands. For many practical applications, these approximate solutions are quite acceptable.

2.4.2 Escaping from 'local peaks'

As just noted, a recognised feature of heuristic search techniques like hill climbing is that the search process may reach solutions to the search problem which are relatively good but are not the best that may be found. With all but the very smallest examples, it is not possible to prove that a given solution is the best

possible solution. With every solution, there is normally the possibility that a better solution may exist elsewhere in the search space.

If, for a given solution, we wish to discover whether a better one may be found elsewhere, it is necessary for the search process to be able to move 'down hill' from the local peak, in the hope that, after some backtracking, a route may be found to something which is 'higher' than the local peak. Alternatively, search may proceed along two or more parallel or pseudoparallel paths and should be allowed to continue even when one or more peaks have been found - to allow for the possibility that paths which by-pass the peaks which have been found may lead to other peaks which are even higher.

In the present context, the need to be able to escape from local peaks means that the search process needs to be able to create alignments yielding relatively poor compression of New in terms of Old. It has been found in practice with the SP61 and earlier models (see Section 2.6, below) that, notwithstanding the conjecture on which this research is based (presented at the beginning of Section 2), it can be advantageous on occasions for the system to create alignments in which IC is very small or even negative.

2.5 'New' and 'Old' and established concepts in computing

In case concepts like 'New' and 'Old' seem too far removed from computing as normally understood, it may be useful at this stage to indicate the direction in which these proposals are going. To this end, Table 1 shows how, in the current proposals, concepts of New and Old may be mapped on to established concepts in computing.

2.5.1 Unsupervised inductive learning

In keeping with remarks at the beginning of Section 2 about the origins of the MLE principle as a key to understanding unsupervised inductive learning, this kind of learning - shown first in Table 1 - provides the overall framework for these ideas.

It is envisaged that compression of any reasonably large body of information will normally be done in an incremental manner, processing one section at a time:

- In keeping with the use of heuristic techniques to accommodate very large search spaces, incremental processing means that, at any one time, the space of possible alignments can be significantly smaller than if the body of information is processed all at once.
- This incremental approach to compression is convenient also when New information is supplied in an incremental manner as it often is. In this case, processing can start immediately without the need to wait until all the information has been received.

In this general framework, it is envisaged that, initially, Old is empty. The first section of New is received or selected and immediately added to Old. It is then processed and compressed as far as possible in terms of patterns in Old. At this early stage, the only compression that can be achieved is due to redundancies that may be present within the first section from New.

<i>Area of application</i>	<i>New</i>	<i>Old</i>
Unsupervised inductive learning	'Raw' data.	Grammar or other knowledge structure created by learning.
Parsing	The sentence to be parsed.	The grammar used for parsing.
Pattern recognition and scene analysis	A pattern to be recognised or scene to be analysed.	The stored knowledge used to recognise one pattern or several within a scene.
Databases	A 'query' in SQL or other query language.	Records stored in the database.
Expert system	A 'query' in the query language for the expert system.	The 'rules' or other knowledge stored in the expert system.
Computer program	The 'data' or 'parameters' supplied to the program on each run.	The computer program itself.

Table 1: The way in which the concepts of 'New' and 'Old' in this research appear to relate to established concepts in computing.

In all subsequent stages, processing is done in the same way: each new section of New is added to Old, a set of multiple alignments are formed between New and Old and the best one is selected as a basis for encoding and compressing New in terms of Old. As successive sections of New are processed, the range of patterns in Old will gradually increase so that, generally, it will become progressively easier to find good matches and useful unifications.

At every stage, the system attempts to encode New information using 'codes' or 'tags' which are attached to patterns in Old. If suitable tags are not present, the system creates new ones and attaches them as required to patterns or parts of patterns in Old.

2.5.2 Other aspects of computing

It is envisaged that each of the other manifestations of computing which are shown in Table 1, and others, may be understood as one *part* of the inductive learning process described in the last subsection. Each of these kinds of computing may be seen as being analogous to the processing of one section of New so that, via the formation of MAs, it is compressed in terms of existing patterns in Old using existing codes. The example in Section 2.2.2 illustrates this idea.

2.6 A working model

With the exclusion of the processes for laying down new patterns in Old, modifying existing patterns in Old and attaching new codes in appropriate places, the concepts which have been outlined above are embodied in a software model, SP61, developed as a test-bed for these ideas and as a vehicle for demonstrations. It is envisaged that the next phase in the development of the model will give it a capability for unsupervised inductive learning: the ability to lay down new patterns in Old, modify existing patterns in Old and assign new codes in appropriate places.

A description of the model in its current form is presented in [Wolff 98a] with a somewhat less detailed description in [Wolff 99]. A fuller description of a similar but slightly earlier version of the model may be found in [Wolff 98d2] with a briefer description in [Wolff 98d1]. Examples from these and earlier versions may be found in the sources cited in Section 1.2. All the examples of alignments which are shown later in this article are output from SP61, edited as necessary to fit each alignment onto the page.

When the concepts and the model are more mature, it is intended that the model will form the basis for the development of an SP system for practical applications.

2.7 Related ideas

Since the primary goal in the development of the ICMAUS framework has been to integrate concepts across a wide range of subfields of computing, it is not altogether surprising that the framework has a family resemblance to other systems. The ability of the ICMAUS framework to model a range of kinds of computing systems was detailed in Section 1.2.

This section notes of some systems with points of similarity with the ICMAUS scheme:

- The GAMMA parallel programming model [Murthy and Krishnamurthy 95] is based on a chemical reaction model in which the datastructure is a bag or multiset. The computations are interpreted as a succession of chemical reactions consuming the elements of the multiset and producing new elements according to specific rules. Computations are achieved via two basic mechanisms: searching for elements of the multiset that satisfy the reaction conditions and, for each element found, the execution of relevant actions. Any number of reactions may be performed in parallel provided they operate on disjoint sets of elements. Where the reaction conditions select two or more elements, the choice of elements may be made probabilistically.
- A 'classifier system' [Forrest 91] comprises a set of production rules operating in a high-parallel environment, a 'bucket brigade' learning algorithm for adjusting weights on rules and a genetic algorithm for the learning of new rules.
- More generally, rule-based programming is a simple scheme with a wide range of applications (See, for example, [Krishnamurthy and Krishnamurthy 99]). Computations are achieved by the interaction of relatively simple elements (rules) in an 'object space' that produce new elements or the same elements

with modified attributes. Within disjoint subsets of the object space, interactions may proceed in parallel. Pattern matching is the basis of how elements are selected. As with the GAMMA model, rule-based programming may be adapted to operate in a non-deterministic, probabilistic manner.

- The TREAT algorithm [Miranker 90] is a matching algorithm designed for efficient pattern matching in a production rule system, running on a specific high-parallel architecture ('DADO'). As with other systems described above, pattern matching and a high-parallel environment are prominent features of the system.

The ICMAUS framework resembles these systems in the use of many relatively simple standardised entities as the basis of knowledge representation and in the emphasis on pattern matching in the way knowledge is processed. The high-parallel environment finds an echo in the high-parallel form of the projected 'SP' computing system, based on the ICMAUS abstract framework. The probabilistic dimension of the ICMAUS scheme is another feature shared with schemes like those just mentioned.

Perhaps the most important difference between these systems and the ICMAUS framework is in the intended scope of the system. By conjecture, the scope of the ICMAUS framework is as broad as computing itself: nothing is taken for granted including such seemingly basic notions as 'variable', the number system, negation, comparisons like 'greater than' or 'less than', and so on. The research aims, amongst other things, to provide an interpretation of concepts like these. Also distinctive of the ICMAUS framework is the emphasis on IC as a unifying theme and, by conjecture, unification of matching patterns as the sole mechanism for achieving IC. Other differences are that 'patterns' in the ICMAUS scheme are even simpler than production rules (patterns lack a rewrite arrow and are without any distinction between 'condition' and 'action') and that multiple alignment is prominent in the ICMAUS framework in a way that it is not in other systems. More controversially, perhaps, the probabilistic dimension of the ICMAUS scheme [Wolff 99, Wolff 98a, Wolff 98b, Wolff 98c] is intrinsic to the basic conceptual framework in a more fundamental way, perhaps, than it is in other schemes.

2.7.1 DNA computing

[Adleman 94] demonstrated that simple versions of the Hamiltonian path problem could be solved using DNA in solution (see also [Adleman 98]). Given the prominence of multiple alignment in the ICMAUS framework and given that MA is often associated with the analysis of DNA molecules, one might naturally assume a relationship between DNA computing and the ICMAUS scheme.

The main significance of DNA computing in relation to the ICMAUS concepts is probably that chemical reactions with DNA (and other molecules) provide a means of matching patterns and this may be done with massive parallelism. Thus potentially, this mode of computing provides a vehicle for the pattern matching required in the ICMAUS scheme and the high levels of parallelism which may help to achieve useful speeds.

In Adleman's first experiments the pattern matching was an all-or-nothing kind, not in itself appropriate for the kind of partial matching required for ICMAUS in its more fully developed forms. However, later work

[Baum and Boney 96] has shown that pattern matching with DNA can support the more sophisticated kinds of heuristic processing needed to find good partial matches between patterns.

3 Universal Turing Machine and Post Canonical System

In its standard form [Turing 36-7], a UTM comprises a 'tape' on which symbols may appear in sequence, a 'read-write head' and a 'transition function'. In each of a sequence of steps, a symbol is read from the tape at the current position of the head and then, depending on that symbol, on the transition function and the current 'state' of the head, a new symbol is written on the tape, the state of the head is changed, and the head moves one position left or right.

A more detailed description of UTMs is not needed here because the arguments to be presented take advantage of the fact [Minsky 67, chapters 10 to 14] that the operation of any UTM can be modelled with a PCS [Post 43]. In this section, I shall describe the workings of a PCS and then, in Section 4, I shall try to show how the operation of a PCS, and thus a UTM, may be understood in terms of ICMAUS.

3.1 The structure of a PCS

A PCS comprises:

- An **alphabet** of primitive **symbols** ('letters' in Post's terminology),
- One or more **primitive assertions** or **axioms** (strings of symbols which can often be regarded as 'input').
- One or more **productions** which can often be regarded as a 'program'.
- Although this is not normally included in formal definitions of the PCS concept, it is clear from how the system is intended to work (see Section 3.2 below), that the PCS also includes mechanisms for **matching patterns** and for **searching** for matches between leading substrings in the input pattern and the left-hand ends of the productions.

Each production has this general form:⁷

$$g_0 \$_1 g_1 \$_2 \dots \$_n g_n \rightarrow h_0 \$'_1 h_1 \$'_2 \dots \$'_m h_m$$

where "Each g_i and h_i is a certain fixed string; g_0 and g_n are often null, and some of the h 's can be null. Each $\$_i$ is an 'arbitrary' or 'variable' string, which can be null. Each $\$'_i$ is to be replaced by a certain one of the $\$_i$." [Minsky 67, pp. 230-231].

In its simplest 'normal' form, a PCS has one primitive assertion and each production has the form:

$$g \$ \rightarrow \$ h$$

⁷ Spaces between symbols here and in other examples have been inserted for the sake of readability and because it allows us to use atomic symbols where each one comprises a string of two or more characters (with spaces showing the start and finish of each string). Otherwise, spaces may be ignored.

where g and h each represent a string of zero or more symbols, and both instances of '\$' represent a single 'variable' which may have a 'value' comprising a string of zero or more symbols.

It has been proved [Post 43] that any kind of PCS can be reduced to a PCS in normal form (see also [Minsky 67, chapter 13]). That being so, this kind of PCS will be the main (but not exclusive) focus of our attention.

3.2 How the PCS works

When a PCS (in normal form) processes an 'input' string, the first step is to find a match between that string and the left-hand side of one of the productions in the given set. The input string matches the left hand side of a production if a match can be found between leading symbols of the input string and the fixed string (if any) at the start of that left-hand side, with the assignment of any trailing substring within the input string to the variable within the left-hand side of the production.

Consider, for example, a PCS comprising the alphabet 'a ... z', an axiom or input string 'a b c b t', and productions in normal form like this:

$$\begin{aligned} a \$ &\rightarrow \$ a \\ b \$ &\rightarrow \$ b \\ c \$ &\rightarrow \$ c \end{aligned}$$

In this example, the first symbol of the input string matches the first symbol in the first production, while the trailing 'b c b t' is considered to match the variable which takes that string as its value. The result of a successful match like this is that a new string is created in accordance with the configuration on the right hand side of the production which has been matched. In the example, the new string would have the form 'b c b t a', derived from 'b c b t' in the variable and 'a' which follows the variable on the right hand side of the production.

After the first step, the new string is treated as new input which is processed in exactly the same way as before. In this example, the first symbol of 'b c d t a' matches the first symbol of the second production, the variable in that production takes 'c d t a' as its value and the result is the string 'c b t a b'.

This cycle is repeated until matching fails. It should be clear from this example that the effect would be to 'rotate' the original string until it has the form 't a b c b'. The 't' which was at the end of the string when processing started has been brought round to the front of the string. This is an example of the "rotation trick" used by [Minsky 67, Chapter 13] in demonstrating how a PCS in normal form can model any kind of PCS.

With some combinations of alphabet, input and productions, the process of matching strings to productions never terminates. With some combinations of alphabet, input and productions, the system may follow two or more 'paths' to two or more different 'conclusions' or may reach a given conclusion by two or more different routes. The 'output' of the computation is the set of strings created as the process proceeds.

3.3 Other examples

For readers unfamiliar with this kind of system, two other examples are included here to show more clearly how a PCS may achieve 'computing'. The first example is based on two examples from [Minsky 67, Chapter 12] showing how odd and even unary numbers may be generated. The second example is from the same source. Other examples may be found in the same chapter.

3.3.1 Generating numbers in unary notation

In the unary number system, $1 = '1'$, $2 = '1\ 1'$, $3 = '1\ 1\ 1'$ and so on. The recursive nature of the unary number system can be expressed very clearly and succinctly with a PCS like this:

- Alphabet: the single symbol 1.
- Axiom: 1.
- Production: If any string '\$' is a number, then so is the string '\$ 1'. This can be expressed with the production:

$$\text{\$} \rightarrow \text{\$ } 1$$

It should be clear from the description of how the PCS works, above, that this PCS will generate the infinite series of unary strings: '1', '1 1', '1 1 1', '1 1 1 1', '1 1 1 1 1' etc.

Less obvious, perhaps, is that the same PCS can be used to recognise a string of symbols as being an example of a unary number. This is done by using the production in 'reverse', matching a character string to the right hand side of the production, taking the left hand side as the 'output' and then repeating the right-to-left process until only the axiom will match.

3.3.2 Generating palindromes

To quote [Minsky 67, p. 228]: "The 'palindromes' are the strings that read the same backwards and forwards, like *cabac* or *abcbbcba*. Clearly, if we have a string that is already a palindrome, it will remain so if we add the same letter to the beginning and end. Also, clearly, we can obtain all palindromes by building in this way out from the middle." Here is his example:

- Alphabet: a, b, c.
- Axioms: a, b, c, aa, bb, cc.
- Productions:

$$\begin{aligned} \text{\$} &\rightarrow \text{a } \text{\$ } \text{a} \\ \text{\$} &\rightarrow \text{b } \text{\$ } \text{b} \\ \text{\$} &\rightarrow \text{c } \text{\$ } \text{b} \end{aligned}$$

Although this example is not in normal form, it should be clear how it generates all the palindromes for the given alphabet. As with the previous example, this PCS may be used to recognise whether or not a string of characters is a palindrome by using the productions in 'reverse'.

4 ICMAUS and the operation of a PCS

It is not hard to see that a successful match between a leading substring in an input string and the leading substring in a PCS production may be interpreted in terms of the alignment and unification of patterns, as outlined in Section 2. What is less obvious is how concepts of alignment and unification might be applied to the processes of matching a trailing string of symbols to the variable, assigning it as a value to the variable and incorporating it in an output string.

4.1 Modelling one step of the "rotation trick"

In the proposed SP framework (ICMAUS), the first PCS described above (for the 'rotation' of a string) may be modelled using the patterns shown in Figure 4. Regarding these patterns:

- The pattern under the heading 'New' corresponds to the axiom or 'input'.
- The four patterns on the left under the heading 'Old' may be seen as a representation of the alphabet.
- The first three patterns on the right correspond to the three productions of the PCS. As we shall see, the pair of symbols, '\$ #\$', in each pattern function as if they were a 'variable'. There is no rewrite arrow ('→') and only one instance of the 'variable'.
- As we shall see, the last pattern on the right ('\$ L #L \$ ## #') is, in effect, a recursive definition of the concept of 'any string of the letters in the given alphabet'. This is comparable with the production shown in the example in Section 3.3.1 which expresses the recursive nature of the unary number system. It is, in effect, a 'type definition' for the variable defining the infinite set of alternative strings (composed from the given alphabet) which the variable may take.⁸

In these patterns, none of the symbols have any 'hidden' meaning. In particular, the symbols '\$', '#\$', 'L', '#L', 'P' and '#P' (which may be described, informally, as 'service' symbols) have exactly the same formal status as other symbols ('a', 'b' etc) and enter into matching and unification in the same way.⁹

4.1.1 One step

Figure 5 shows the best alignment (in terms of IC) found by SP61 with the 'input' pattern in New and the other patterns in Old. In the figure, the repeated appearances of the pattern '\$ L #L \$ ## #' represent a single instance of that pattern in accordance with the generalisation of the multiple alignment problem described in Section 2.2.1. The same is true of the two appearances of the pattern 'L b #L'.

Unification of the matching symbols in Figure 5 has the effect of 'projecting' the alignment into a single sequence, thus:

⁸ Readers will note that the pattern '\$ L #L \$ ## #' contains two 'variables': the pair of symbols '\$ #\$', already considered, and also the pair of symbols 'L #L' which can take any of 'a', 'b' or 'c' as its 'value'.

⁹ Although it is true in general for the ICMAUS framework that all symbols have the same status, the principle should perhaps be qualified here since, at the end of each cycle, it is proposed below that the 'service' symbols are removed from the 'output' string leaving only the 'data' symbols for further processing.

New

a b c b t

Old

L a #L	P a \$ ## a #P
L b #L	P b \$ ## b #P
L c #L	P c \$ ## c #P
L t #L	\$ L #L \$ ## \$

Figure 4: SP patterns modelling the first example of a PCS described in Section 3.1. An interpretation of these patterns is given in the text.

P a \$ L b #L \$ L c #L \$ L b #L \$ L t #L \$ ## \$ ## \$ ## \$ ## \$ a #P.

Notwithstanding the interpolation of instances of 'service' symbols like 'P', '\$', 'L', '#L' etc, this sequence contains the subsequence 'a b c b t' corresponding to the 'input' and also the subsequence 'b c b t a' corresponding to the 'output' of the first step of our first example of a PCS.

In this example, the subsequence 'b c b t' corresponding to the contents of the 'variable' is shared by the input and the output thus removing the need for the rewrite arrow in the PCS. An analogy for this idea is the way Welsh and English are sometimes conflated in bilingual signs in Wales. The phrase 'Cyngor Gwynedd' in Welsh means 'Gwynedd Council' in English. So it is natural, in bilingual signs put up by Gwynedd Council, to represent both the Welsh and the English forms of the name using the words 'Cyngor Gwynedd Council'. In this example, the word 'Gwynedd' serves both the Welsh version of the name and the English version in much the same manner that, in our example above, the contents of the variable serves both the input string and the output string.

4.1.2 Repetition of steps

The second and subsequent steps may proceed in the same way. At the end of each step, we may suppose that the 'service' symbols are stripped out and the sequence from the contents of the 'variable' onwards is presented to the system again as New. When 't' reaches the front of the string, there is no production with a leading 't' which means that New at that stage cannot be fully matched. In this example, this may be taken as a signal that the rotation is complete.

In Minsky's example (which takes too much space to reproduce here), the presence at the beginning of the string of 'T1' (which may be equated with 't' in our example) causes other productions to 'fire', leading the processing into other paths.

4.2 Other examples

This subsection shows how the second and third examples of a PCS which were described above may be modelled as ICMAUS.

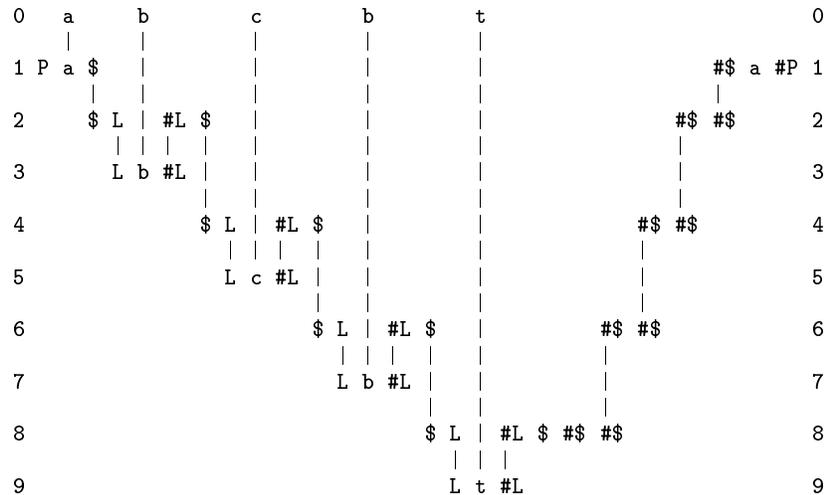

Figure 5: The best alignment (in terms of IC) found by SP61 using the patterns shown in Figure 4 as described in the text.

4.2.1 Unary numbers and ICMAUS

Figure 6 shows two patterns to model the example of a PCS for generating unary numbers (Section 3.3.1, above). The first pattern corresponds with the axiom in the PCS and the second one corresponds with the production in the PCS.

New

1 (Other options for New are described in the text)

Old

\$ \$ # \$ 1 # \$

Figure 6: Patterns for processing by SP61 to model a PCS to produce or recognise unary numbers (Section 3.3.1).

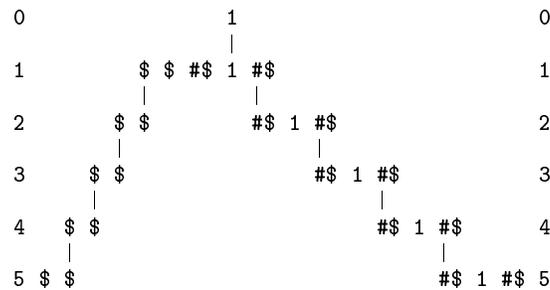

If the two symbols '\$ # \$' in the body of the pattern '\$ \$ # \$ 1 # \$' have nothing between them, the pattern represents '1' by itself. Otherwise, the first and last symbols in the pattern can be matched with the same pair in the body of the pattern - and this pair is followed by '1'. Thus the pattern '\$ \$ # \$ 1 # \$' may be read as "A unary number is '1' or any unary number followed by '1'".

If the first of the two patterns is supplied to SP61 as New and the second is placed in Old, the program will generate a succession of 'good' alignments,

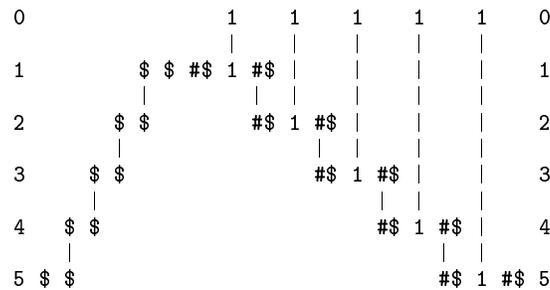

one example of which is shown in Figure 7 (a). If it is not stopped, the program will continue producing alignments like this until the memory of the machine is exhausted.

If we project the alignment in Figure 7 (a) into a single sequence and then ignore the 'service' symbols in this example ('\$' and '#\$'), we can see that the system has, in effect, generated the unary number '1 1 1 1 1'. We can see from this example how the alignment has captured the recursive nature of the unary number definition.

Readers may wonder whether it makes any sense to 'compress' something as small as '1' using a relatively large pattern like '\$ \$ # \$ 1 # \$' which itself contains '1', especially if it is repeated several times in an alignment. Relevant discussion may be found in Section 3.3, below.

(a)

(b)

Figure 7: (a) One of many 'good' alignments produced by SP61 from the patterns in Figure 6. (b) The best alignment (in terms of compression) produced by SP61 with '1 1 1 1 1' in New and, in Old, the patterns from 'Old' in Figure 6.

Figure 7 (b) shows the best alignment produced by SP61 when '1' in New is replaced by '1 1 1 1 1'. This alignment is, in effect, a recognition of the fact that '1 1 1 1 1' is a unary number. It corresponds to the way a PCS may be run 'backwards' to recognise input patterns but, since there is no left-to-right arrow

4.3 Information compression and the operation of a PCS

It should be clear from the foregoing discussion and examples that the process of matching a string of symbols with one production in a PCS may always be modelled as the formation of an alignment as defined in this research.

Given the conjecture which provides the inspiration for this research (described at the beginning of Section 2), a pertinent question to ask is: "Does every alignment of this kind always yield compression of New in terms of patterns in Old?"

The answer to this question depends on the details of how the encoding of New in terms of Old is done, including assumptions on which any given method is based. It is certainly possible to devise encoding methods where the answer to the question, above, would be "no". With the method used in SP61 (outlined in Section 2.3), the answer is "yes", provided that a key assumption is made, described and discussed in the following subsections.

4.3.1 When an encoding has fewer symbols than New

Let us consider, first of all, an example where the conclusion is likely to be uncontroversial even with very conservative assumptions. Let us suppose that New contains the sequence 'a l o n g s e q u e n c e o f s y m b o l s' and that Old contains, amongst others, the pattern 'P 1 a l o n g s e q u e n c e o f s y m b o l s #P'.

With this example, it should be clear that New can be aligned with the matching sequence of symbols in the pattern from Old and that New may be encoded in terms of this pattern as something like 'P 1 #P'. The encoding is much smaller than New in terms of numbers of symbols and, if we assume that a fixed number of bits is used for the encoding of every symbol, there is also compression in terms of bits of information.

4.3.2 When an encoding has as many or more symbols than New

If New contains only one symbol, 'a' and if Old contains patterns like 'P 1 a #P', 'P 2 b #P', and so on, one would naturally assume that no positive compression could be achieved. If 'a' in New is aligned with 'a' in 'P 1 a #P', then its encoding would be 'P 1 #P' or something similar. If a fixed number of bits is used for the encoding of every symbol, then each of these encodings represents negative compression.

In SP61, it is assumed that every symbol in New is larger than the theoretical minimum needed to discriminate one symbol from another - which means, in effect, that each symbol in New is assumed to contain redundancy. This is like assuming that each symbol in New represents a relatively large chunk of information like 'j o h n' in the example in Section 2.2.2. The assumption that each symbol in New is relatively large is coupled with a calculation of two sizes for symbols in New: a notional 'actual' size which is relatively large and a 'minimum' size which is the size of a code which may be used to represent the symbol and is close to the theoretical minimum. For clarity in this discussion, each symbol from New in its actual size will be represented directly as 'a', 'b' etc, while the code for a symbol from New will be represented with the same characters and 'prime', e.g., 'a'', 'b'' etc.

Let us suppose that 'a b c b t' in New is aligned with patterns from Old as shown in Figure 5. In this case, the encoding of New in terms of Old would be 'P a' b' c' b' t' #P' or something similar. This encoding has more symbols than the sequence from New which is being encoded so, on a superficial reading, there should be zero or negative compression. But if the 'actual' size of each symbol from New is, say, 20, bits, if the 'minimum' size of each symbol from New and each of 'P' and '#P' is, say, 4 bits, then the encoding above represents a compression of $(5 \times 20) - (7 \times 4) = 72$ bits.

4.4 Redundancy in the operation of digital systems

The assumption, above, that each symbol in New contains redundancy may seem like an *ad hoc* assumption to salvage the conjecture on which this research is based. However, a little reflection may convince us that the assumption has some justification.

4.4.1 Computing with '0' and '1'

One of the attractions of digital systems is that they are relatively robust in the face of noise. If, as is normally the case, a binary alphabet is used, the two symbols (normally '0' and '1') are typically represented by two different voltages whose values are different enough to ensure that the electronics can discriminate them with little or no error through billions of computations.

Given that the technology is capable of discriminating a much larger number of different voltages than two, the use of only two voltages is analogous to the use of only 'A' and 'Z' from an alphabet of 26 symbols. Since an alphabet of 26 symbols requires, in round figures, $\log_2 26 \simeq 5$ bits of information for each symbol (assuming that they are equiprobable), the two symbols 'A' and 'Z' are expressed with 5 times as many bits as the theoretical minimum which is 1.

If the analogy is accepted as valid, then we may conclude that digital computing is based on the provision of redundancy in the 'bedrock' of its computations. Reducing the redundancy at this level (by bringing the difference in voltages closer to the threshold of what the electronics can discriminate) would cause errors to increase. Would any computing be possible if all redundancy at this level were eliminated?

4.4.2 Identifiers, addresses and codes

If we consider 'higher' levels in the organisation of digital computers, we find that there is typically much redundancy in how entities of different kinds are identified.

This is clearly true of identifiers like the names of files, names of tables and fields in databases, and the names of functions, variables and so on in computer programs. It may be objected with some justice that this redundancy exists primarily to serve the psychological needs of humans who must read and remember these identifiers and that the identifiers are all converted into addresses on disk or in computer memory which is where 'real' computing is done.

But addresses to locations in computer memory also contain redundancy. It is rare for any application to use every location which has been provided, so

more bits are needed to identify each location than are strictly necessary. It may be objected, with justice, that this is because, with current technology, we cannot provide new memory locations only when required. More to the point, perhaps, is that some memory locations are likely to be used more often than others but the addressing system does not take advantage of this by assigning short addresses to frequently-accessed locations and longer addresses to locations which are accessed rarely. Indirect addressing may go partly down this road but it is only an approximate solution.

In a similar way, fixed-length codes for symbols or other entities (e.g., the 8-bit codes of the ASCII character set) are convenient but are normally quite redundant because they do not exploit variations in the frequencies with which different codes are used.

4.4.3 Huffman coding

Of course, there are well-known techniques for constructing variable-length codes to take advantage of variations in frequency. The best-known of these is Huffman coding (see [Cover and Thomas 91]).

It is often said that the sizes of Huffman codes are at the theoretical minimum. In one sense, this is true but it is slightly misleading. In order to 'parse' a sequence of binary symbols representing a sequence of Huffman codes, it is necessary to use the trie which was created alongside the Huffman codes. The codes themselves may be minimal but, in themselves, they are unusable. The additional information needed to specify the trie may be seen as redundancy within the whole system.

4.4.4 Discussion

This quick review of the workings of digital computers has shown that redundancy pervades the system in the way that symbols and other entities are identified. And even where it seems that all redundancy has been eliminated, it can be argued that it is present in a covert form.

Redundancy equates with 'structure'. If a computing system, including its programs, is totally lacking in redundancy then it is totally unstructured - which means that it is totally random. A system which is totally random and unstructured is no system at all. It certainly cannot support the highly structured and predictable kinds of information processing that we know as 'computing'. In a similar way, meaningful computing depends on the existence of redundancy at some level in the input data, even if it is only in the symbolic structure of the data.

These considerations suggest that the deliberate introduction of redundancy into the symbols in New in the SP model is more than an *ad hoc* 'fix' for a theoretical anomaly. It seems that computing depends in a fundamental way on the existence of redundancy at some level both in the structure of the computer and its programs and also in the data to be processed by the computer.

5 Augmentation of established models of computing

Section 4 has described, with examples, how the operation of a PCS in normal form may be understood as ICMAUS. Since it is known that any PCS may be

modelled by a PCS in normal form ([Post 43], [Minsky 67, Chapter 13]), we may conclude, tentatively, that the operation of any PCS may be interpreted in terms of ICMAUS. Since we also know that any UTM may be modelled by a PCS [Minsky 67, Chapter 14] we may also conclude, tentatively, that the operation of any UTM may be interpreted in terms of ICMAUS.

Although the operation of a PCS or UTM may understood in terms of ICMAUS, it does not require the full range of capabilities of a well-developed ICMAUS system. Matching in a PCS or UTM is done in a relatively constrained manner (Section 2.4.1) which does not require sophisticated search.

What is envisaged for the proposed SP system is a much more fully developed realisation of ICMAUS mechanisms including well-developed abilities for heuristic search, for finding 'good' partial matches between patterns and for building a wide variety of alignments amongst patterns.

Figure 10 shows a schematic representation of the proposed 'SP' computer with a schematic representation of a conventional computer (or UTM or PCS etc) for comparison. The next two subsections consider each of these in turn.

5.1 Conventional computers (UTM, PCS etc)

Schematically, the conventional computer (or UTM or PCS etc) comprises the core machine (C), together with software across a range of applications (S).

In terms of the ideas described in Sections 2 and 4, we may suppose that C in the conventional computer may be interpreted as ICMAUS with relatively simple search mechanisms which operate in a somewhat rigid 'clockwork' manner.

In a PCS, searching and matching occurs when the input string is compared with the left-hand sides of productions. In a UTM, searching and matching occurs when a symbol newly read from the tape, together with a symbol representing the state of the read-write head, is compared with the left-hand part of each of several tuples in the transition function. Where exact matches are found, the right-hand part(s) of the corresponding tuples control (in a deterministic or non-deterministic manner) what happens next.

In a conventional computer, one manifestation of searching and matching is the process by which an item in memory is accessed using the address of that item. This may be seen as a process of searching through addresses in memory until a match is found for the given address. Accessing an item in memory is served by logic circuits which, with great speed, eliminate areas of memory progressively until the item is found.

This kind of highly constrained form of searching and matching has advantages for certain kinds of problem which can be solved with great accuracy and speed. The penalty is that other kinds of problem which require more flexibility cannot be solved unless additional mechanism is provided in S.

Thus, owing to the limitations of C in the conventional computer, many applications within S contain additional ICMAUS mechanisms designed to make good the deficiencies of the core mechanisms. Similar mechanisms are provided repeatedly in diverse applications. For example, search in various forms is found in database systems, expert systems, parsers, compilers, text editors and DTP software (especially software for spelling checking and correction), spreadsheets, genetic algorithms of various kinds, data mining software, and many other more or less specialised kinds of software. Thus there is much more of this kind of

repetition than is suggested by the three instances of ICMAUS shown in the 'S' part of the conventional computer as portrayed in Figure 10.

As already indicated, ICMAUS mechanisms provided in C of the conventional computer do not exploit the full potential of this type of mechanism. The ICMAUS mechanisms in S are also incomplete because, in general, each one provides only what is required for a specific application and, out of those requirements, they normally provide only what is missing from C. Hence, to show that these instances of ICMAUS mechanisms in C and S of the conventional computer are not fully developed, they are represented in Figure 10 using relatively small type.

What else is in S? In general, the parts of S which are not ICMAUS mechanisms are domain-specific knowledge about such things as the rules of accounting, the classes of objects found in a particular organisation (each with its associated data structures and methods), the laws of thermodynamics, aerodynamics or topology, and many other concepts across all the many areas where computers can be applied.

5.2 The proposed 'SP' computer

In the proposed SP computer, the core mechanism (C) comprises ICMAUS mechanisms developed as fully as our understanding and available resources allow. Although C in the SP computer is probably larger and more complex than C in the conventional computer, the anticipated pay-offs are the elimination of repeated instances of ICMAUS in S giving an overall simplification of the system (C + S) and better integration across applications.

The key difference between ICMAUS in C in a conventional computer and ICMAUS in C of an SP computer seems to be that, without additional programming, the former is restricted to exact matches between sequences of symbols whereas the latter should have a well-developed capability for finding good partial matches between sequences of symbols or, in advanced versions, good partial matches between arrays of symbols in two or more dimensions. The core of the projected SP computer should also contain mechanisms for building multiple alignments of the kind described in Section 4.

5.2.1 Constraining the SP computer to behave like a conventional computer

Although the SP computer should be able to find good partial matches between arrays of symbols, it should be possible to restrict it to exact matches between sequences of symbols if that is required for any particular application. Thus, with suitable constraints (see Section 2.4.1), the SP computer may be made to function, when required, as if it was a conventional computer.

5.3 Minimum Length Encoding in the design of computers?

The principles just described are similar to the principle of Minimum Length Encoding in grammar induction (described in Section 2.1).

In the case of grammar induction, the principle requires a search for a grammar which minimises the size of the grammar together with the size of the sample

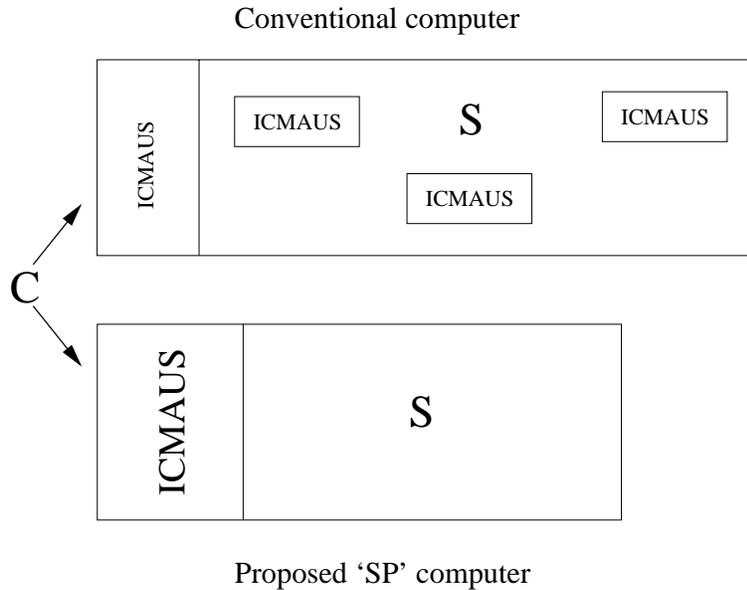

Figure 10: Schematic representation of a conventional computer and the proposed 'SP' computer in terms of the ICMAUS proposals. **Key:** C = the 'core' of the conventional computer and of the SP computer; ICMAUS (in small type) = ICMAUS mechanisms (described in Section 2) in various relatively restricted forms. ICMAUS (in large type) = ICMAUS mechanisms in a relatively fully developed and generic form; S = software to cover a wide range of applications. In the conventional computer, S includes many instances of (small) ICMAUS - more than the three instances shown here. It is assumed that the data to be processed is the same for both computers.

when it is encoded in terms of the grammar. This means compressing the sample and making sure that the grammar which is derived from the sample is counted as part of the 'cost' of compression.

In the case of computer design, we are aiming to compress the system including both the 'core' of the computer and all its software. Very roughly, we may equate C in Figure 10 with the grammar in grammar induction and we may equate S in computers with the data in grammar induction. In the same way that an increase in the size of a grammar can mean an overall decrease in the size of grammar and data taken together, an increase in the size of C can mean an overall reduction in (C + S), as suggested in Figure 10.

5.4 Extending established ideas

The principles illustrated in Figure 10 are not new. The same kinds of principle provide the motivation for the creation of database management systems or expert system shells. In this type of application, and others, a system is created which can be used as the foundation for a range of applications of one kind, thus saving the need to reprogram the basic mechanisms in each application. In accordance with remarks above about cost and quality, the use of database man-

agement systems and expert system shells can mean dramatic savings in costs and gains in quality compared with programming each application individually.

What is different about the present proposals is that their anticipated scope is much wider than the scope of a database management system or of an expert system shell. Evidence of the possible scope of the system is provided in the sources cited in Section 1.2.

5.5 Design of an SP computer

Given current technology, the most straightforward way to create an SP computer is to program it as a software virtual machine running on a conventional computer. Although the SP61 model has been created in this way as a test-bed and demonstrator for theoretical concepts, it is also, in effect, a realisation of an SP computer.

On longer time-scales, creating an SP computer in this way is almost certainly not the best way to do it. Reasons why this should be so are considered in the next two subsections.

5.5.1 New hardware needed

In the 'core' of a conventional computer (as in the basic mechanisms of the UTM and PCS), mechanisms for searching and matching are not programmed. In the case of the UTM and the PCS, the mechanisms are part of the definition. In digital computers, notwithstanding the existence of 'microcode', core mechanisms are, in general, provided by dedicated hardware like the logic circuits mentioned earlier for accessing an item in memory by means of its address.

In a similar way, it is not necessary for the search mechanisms in an SP computer to be programmed. Creating these mechanisms by programming a conventional computer is a bit like cleaning the bathroom with a toothbrush (as Goldie Hawn was required to do in "Private Benjamin"). It can be done but the basic tools are clearly not designed for the job. In the long run, it is likely that hardware techniques may be found which meet the requirements of the system more directly.

New hardware does not necessarily mean new *electronic* hardware. There is potential for flexible pattern-matching using light with high levels of parallelism (see next), especially since light rays can cross each other without interfering with each other. As noted previously (Section 2.7.1), there is also potential for searching huge pattern-matching search spaces in parallel using chemicals in solution (or other form), as, for example, in DNA computing.

5.5.2 Parallel processing

Although the estimated time complexity and space complexity of the current SP model are good, the ICMAUS mechanisms are intrinsically 'hungry' for computing power unless they are constrained to work like a conventional computer. One possible solution to this problem is the creation of an SP system as a software virtual machine running on a high-parallel computer comprising many (cheap) conventional processors. This approach is perhaps more promising than a software virtual machine on a single processor. Returning to the toothbrush

analogy, it would be like a cleaning device comprising thousands of toothbrushes - conceivably quite effective.

Alternatives, as before, include new devices based on electronics, light or chemistry, or some combination of those mechanisms.

6 Conclusion

This article has presented the 'SP' concepts in outline and has tried to show how established models of computing may be interpreted in terms of information compression by multiple alignment, unification and search. It has also been argued that established models may be augmented to exploit more fully the potential functionality of the ICMAUS mechanisms.

Although this augmentation would increase the size and complexity of the core computational process, research to date suggests that there could be a reduction in the size and complexity of software - and this could mean an overall saving in the size and complexity of the combination of core system and software. In terms of practicalities, less software should mean lower costs and fewer errors in working systems. There should also be better integration across diverse applications.

In accordance with 'Occam's razor' (and, indeed, with the MLE principle incorporated in the SP theory), a good theory should combine 'Simplicity' with explanatory or descriptive 'Power'. Established models of computing are very simple but they leave many problems unsolved. The conceptual framework described in this article seems to provide an interpretation for established models. At the same time, it suggests how these models may, with advantage, be enlarged. The resulting reduction in Simplicity may be more than offset by an increase in descriptive and explanatory Power.

Acknowledgements

I am grateful to one of the referees of this article for alerting me to the relevance of the rule-based programming paradigm, probabilistic parallel programming based on multiset transformation, classifier systems and the TREAT algorithm, and for helpful comments on the article. Thanks also to the second referee for suggesting DNA computing for inclusion in the article. I am grateful also to Professor Tim Porter of the School of Mathematics, University of Wales, Bangor, for very helpful comments on earlier drafts of this article and discussion of related issues. Many thanks also to Dr Chris Wensley in the same School for useful discussions from time to time of related issues.

A Definitions of concepts

A.1 Basic concepts

Definition 1

A **symbol** is some kind of mark which can be compared with any other symbol. In the context of pattern matching, a symbol is the smallest unit which can

participate in matching: a symbol can be compared (matched) only with another single symbol and the result of matching is either that the two symbols are the same or that they are different. No other result is permitted.

An important feature of the concept of a *symbol*, as it is used in this research, is that, with respect to the way it behaves within the system, it has **no hidden meaning**. In this research, a symbol is *nothing but* a primitive mark which can be discriminated in a yes/no manner from other symbols. There are no symbols like the symbols in an arithmetic function (e.g., '6', '22', '+', '-', '×', '/', '(', ')', etc), each of which has a meaning for the system which is not directly visible.

Any symbol may have a meaning but that meaning must take the form of one or more other symbols which are associated with the given symbol and are explicit and visible within the structure of symbols and patterns.

Although symbols in the proposed framework have no hidden meaning having an effect on how the symbol behaves in the system, they can and often do have a meaning for the human reader.

If two symbols match, we say that they belong to the same **symbol type**. In any system which contains symbols, we normally recognise an **alphabet** of symbol types such that every symbol in the system belongs in one and only one of the symbol types in the alphabet, and every symbol type is represented at least once in the system.

A positive match between two symbols is termed a **hit**. In an alignment of two more *patterns*, one or more unmatched symbols within one pattern between two hits or between one hit and the end of the pattern is a **gap**.

Definition 2

A **pattern** is an array of symbols in one, two or more dimensions. In this article, one dimensional patterns (**sequences** or **strings** of symbols) are the main focus of attention.

The meaning of the term *pattern* includes the meanings of the terms *substring* and *subsequence*, defined next.

Definition 3

A **substring** is a sequence of symbols of length n within a sequence of length m , where $n \leq m$ and where the constituent symbols in the substring are contiguous within the sequence which contains the substring.

Definition 4

A **subsequence** is a sequence of symbols of length n within a sequence of length m , where $n \leq m$ and where the constituent symbols in the subsequence may not be contiguous within the sequence which contains the subsequence. The set of all subsequences of a given sequence includes all the substrings of that sequence.

A.2 The Post Canonical System in normal form

Definition 5

A **Post Canonical System** in normal form is a quadruple $PCS = (A, I, P, S)$, where A is a finite set (alphabet) of one or more symbols (which Post calls

'letters'), I is an 'axiom' or 'input' comprising a finite string of one or more symbols (drawn with replacement from A), P is a finite set of one or more 'productions' and S is a method of searching for a match between a string of symbols and one or more of the productions.¹⁰

Each production has the form:

$$g \$ \rightarrow \$ h,$$

where g and h each represent a string of zero or more symbols (drawn with replacement from S), and both instances of '\$' represent a single 'variable' which may have a value comprising a string of zero or more symbols.

A PCS (in normal form) operates by searching (using the method S) for one or more exact matches between the leading substrings in I and the string g in one or more of the productions (P). Wherever an exact match is found, the trailing substring (if any) is assigned to the variable, \$. The string which comprises the value of '\$' followed by the string h (which may be termed 'output') is then treated as new input, and matches are sought for this input as before. The process terminates if and when no more matches can be found.

A key characteristic of S is that, for any 'input' string (i.e., the original input string or one of the strings formed by the system which are processed in the same way), it should be able to find every production where the string g in the production is an exact match for a leading substring in the input string.

Comments

Notice that any search for a match between a symbol string and the leading symbols of productions can yield more than one positive result - and a given computation may develop two or more 'strands' with further branching at any stage (see [Minsky 67, Chapter 13]. Thus PCSs can accommodate both 'deterministic' and 'non-deterministic' styles of computing.

A.3 The SP System

Definition 6

An SP System is a quadruple $SPS = (A', N, O, S')$, where A' is a finite set (alphabet) of one or more primitive symbols, N is a pattern of symbols ('New'), O is a finite set of one or more patterns of symbols ('Old'), and S' is a search method, different from and, in some sense, more sophisticated than S in a PCS (see below).

Using S' , the system operates by searching for one or more *alignments* (defined next), where each alignment contains N and one or more patterns from O and where each alignment promotes the compression of N by unification of matching symbols in the alignment.

¹⁰ The definition of a PCS given here is drawn from the descriptions in [Post 43] and [Minsky 67] except that S has been identified explicitly as an element of the system. In both Post's and Minsky's accounts, the process of searching for matches between strings and substrings is not formally identified as an element of the system and the descriptions which they give of S are informal. The reason for identifying S explicitly in this article is to emphasise what appears to be the key difference between a PCS (or UTM) and generalised forms of the SP system, as discussed in Section 5.

Definition 7

In the case of one-dimensional patterns,¹¹ an **alignment** is a two-dimensional array of one or more patterns, each one in a separate **row** in the array. The alignment shows sets of two or more matching symbols by arranging the symbols in each set in a **column** of the array.¹² In an alignment, as defined in this research:

- Symbols which are contiguous in a pattern which appears in an alignment, need not occupy contiguous cells in the array.
- Any one pattern may appear one or more times in an alignment.
- Where a pattern appears two or more times in an alignment, no symbol in one appearance of the pattern should ever be shown as matching the same symbol in another appearance of the pattern.
- Any symbol in one pattern may be placed in the same column as any other symbol from the same pattern or another pattern, providing *order constraints* are not violated.

For any alignment, **order constraints** are preserved if the following statement is always true:

For any two rows in the alignment, A and B, and any four symbols, A₁ and A₂ in A, and B₁ and B₂ in B, if A₁ is in the same column as B₁, and if A₂ is in the same column as B₂, and if A₂ in A follows A₁ in A, then B₂ in B must follow B₁ in B.

This condition holds when the two rows contain two different patterns and also when the two rows contain two appearances of one pattern.

Definition 8

A **mismatch** in an alignment occurs when, between two columns in the alignment containing hits, or between one column containing hits and the end of the alignment, there are no other columns containing hits and there are two more columns containing single symbols from two or more different patterns in Old.

Definition 9

The **search space** of an SPS is the set of possible alignments of N and the patterns in O.

¹¹ As previously noted, the concept of an alignment can be generalised in a straightforward manner to patterns of two or more dimensions. But no attempt is made here to provide a formal definition for alignments of patterns of two dimensions or higher.

¹² The fact that, in displaying alignments, it can sometimes be convenient to put non-matching symbols in the same column with lines to mark the symbols that do match (as in Figure 1) is not relevant to the abstract definition of an alignment presented here.

Definition 10

An alignment is **equivalent** to one step in the operation of a PCS if:

- The alignment contains no mismatches.
- Every symbol in I of the PCS can be mapped to an identical symbol in the pattern N in the alignment.
- The order of the symbols in I is the same as the order of the matching symbols in N.
- For the production in the PCS which enters into the given operation, every symbol in that production can be mapped to an identical symbol in a pattern from O which appears in the alignment, and the order of the symbols in the production are the same as the order of the matching symbols in the corresponding pattern.
- For every positive match between two symbols in the operation of the PCS there is a column in the alignment containing a matching pair of symbols. The order of these columns in the alignment must be the same as the order of the corresponding pairs of symbols in the operation of the PCS.
